Solutions with Speed

Comlinear Corporation, located in Fort Collins, Colorado, is a manufacturer and supplier of high-performance analog signal processing components. Comlinear's signal conditioning product line includes high-speed hybrid and monolithic operational amplifiers, buffers, and clamping amplifiers. The data converter product line includes track/hold amplifiers and analog-to-digital converters. The corporate philosophy is to focus development on products that make a significant contribution toward solving customer problems. The result has been the ever-expanding line of high-performance products included in the following pages.

The company is housed in a custom-built facility, which is DESC certified to MIL-STD-1772. Manufacturing, Quality Assurance, Research and Development, Administration and Marketing are centered in this location.

Comlinear's proprietary signal processing components are sold worldwide to a diverse group of commercial, industrial and military customers. Representative application areas include communications (satellite systems, radar, fiber optics), avionics (electronic counter measures, instrumentation), video (high resolution displays, video processing and distribution), and automatic test equipment.

Comlinear believes that a deeply-rooted dedication to quality is a critical path to customer satisfaction. Statistical process control and team quality concepts are approaches used throughout the company to improve quality in activities ranging from new product releases to order processing to shipping. It is only through this comprehensive approach to quality that lasting improvements in all product and service areas can be achieved.

Comlinear's goal is to offer our customers superior products with quality and service second to none.
DISCLAIMER INFORMATION

Warning-Life Support Systems

Comlinear's products are not authorized for use in life support devices or systems without express written authorization from the President of Comlinear Corporation. Life support devices or systems are those which are intended to support or sustain life, and whose failure to perform when properly used in accordance with the instructions provided can be reasonably expected to result in significant personal injury or death to the user.

LIMITATION ON WARRANTY AND REMEDIES

Comlinear makes no warranty with respect to its products except as expressly set forth in its standard conditions of sale. All implied warranties, including any implied warranty of merchantability or fitness for a particular purpose, are hereby disclaimed. Any warranty extended on Comlinear products is limited to the replacement of the defective component and does not cover personal injury, property damage, or incidental, consequential or special damages.

DISCLAIMER

Information on all products and services furnished herein by Comlinear Corporation is believed to be accurate and reliable at the time of this printing. Comlinear reserves the right to make changes to its products and specifications at any time without notice. Comlinear Corporation does not assume responsibility for the use of the products described herein.

The products in this databook are covered under one or more of the following patents:
4,358,739; 4,502,020; 4,628,279; 4,639,685; 4,713,628; 4,757,275; 4,766,367; 4,780,689; 5,049,653 (other patents pending).

### Linear Amplifiers

#### Key Features

- 3dB Bandwidth (MHz)
- Full Power BW (MHz @ V_{in}, R_L)
- Harmonic Distortion (dBc @ 20MHz, 2V_{pp})
- Settling Time (nsec, %)
- Output (V, mA)
- Slew Rate (V/µsec)
- Output Offset Drift (mV/ºC)
- Test Conditions

**NOTES:**

1. The version designation indicates the temperature range and screening level:  
   - C: 0°C to +70°C commercial  
   - J: -40°C to +85°C industrial  
   - I: -40°C to +85°C industrial: hybrid  
   - E: -40°C to +85°C commercial SOIC  
   - K: -55°C to +125°C high-reliability industrial hybrid  
   - L: -55°C to +125°C dice  
   - M: -55°C to +125°C hybrid: high-reliability military  
   - 8: -55°C to +125°C MIL-STD-883 compliant

2. CLC100 and CLC104A are non-inverting, CLC102 is inverting gain.
3. Evaluation boards are available for all hybrid and monolithic integrated circuits. Encased and connectorized versions of the CLC103, CLC203, CLC200, CLC201, CLC220, CLC221, CLC231 and CLC104 are available as well. Contact Comlinear or your local Comlinear representative for details.

*Contact the factory for further information.*

1Indicates new products since 1991 databook.

See the individual product data sheets for details.

Quality excellence is an approach to business based on understanding the customer's needs, and then striving consistently and efficiently to meet those needs with desired products and services.

Comlinear recognizes that pursuing quality excellence will result in both increased customer and employee satisfaction by achieving higher productivity, improved reliability and increased value.

At Comlinear, quality excellence is implemented through a continuous and committed team approach to quality improvement, from senior management through all employees for all activities of the company.

We elevate quality beyond its typical stature as a military mandated program, and foster an environment where it becomes a pervasive operating attitude. Comlinear's ability to deal with the required elements of a quality program is shown by the continual maintenance of our MIL-STD-1772 facility certification, and our MIL-STD-883 compliant, DESC SMD approved, monolithic and hybrid products.

What makes Comlinear a preferred supplier are our efforts to address the competitive challenge in today's market by focusing on the quality of all of our products and services.

Our commitment to product assurance means that we start with the required systems and then enhance them with the most up-to-date quality assurance techniques available. Tools such as SPC, quality improvement teams, and experimental design are all used in an environment of Total Quality.

Application of these techniques is the responsibility of all managers and employees. These techniques, and the desire for continuous quality improvement, are found in areas ranging from accounting, research and development, and computer services to manufacturing processes and shipment.

The Quality Assurance group supports these efforts by providing technical resources in quality engineering for failure analysis, reliability monitoring, and process improvement. Furthermore, quality levels in manufacturing are continually measured and the information is supplied to the responsible managers.

Comlinear will be pursuing assessment and certification to the International Organization for Standardization (ISO), specifications 9000 and 9001. This effort will solidify Comlinear's commitment to fulfilling customer needs and achieving product and service excellence.

PRODUCTS AND TECHNOLOGIES

Comlinear's hybrid circuit manufacturing is located in our MIL-STD-1772 certified production line in Fort Collins, Colorado. Our capabilities include high density thin film substrate fabrication incorporating high precision, high stability tantalum nitride resistors, gold metalization, and alumina substrates. Monolithic microcircuits are fabricated in the U.S.A. using a high speed complementary bipolar integrated circuit process. This combination has demonstrated an actual failure rate for ICs of less than 1.0 FIT in lifetesting.

Both monolithic and hybrid products are available as MIL-STD-883, industrial or commercial levels. DESC SMDs are available for most of our catalog hybrid and monolithic products. Our monolithic products are also available as MIL-STD-883, S (space) level compliant. Though our hybrid products can be processed to selected K (space) level criteria, the final product would not be compliant or certified to MIL-STD-883 or MIL-M-38534, K level.

ENVIRONMENTAL IMPACT/SAFETY AWARENESS

Comlinear is actively pursuing the elimination of ozone depleting substances (ODS) in its manufacturing processes and is persuading its suppliers to comply with the Montreal Protocol and all U.S Federal regulations.

The flammability rating of commercial, plastic DIP, monolithic products is 94V-0 of the UL-94 Flame Class; this rating is subject to change without notification.

The following section outlines the various flows for both the hybrid and the monolithic product lines and provides additional reliability data.
Comlinear has the expertise, product lines and demonstrated reliability to support your space-based systems. In addition, we have the experience and program management necessary to meet the unique demands of processing components to space level MIL-STD-883 or custom flows.

The monolithic product lines have been designed for the robust, reliable assembly and high radiation tolerance necessary for success in the space system environment. Also, a mono-metallic gold wire bonding system is used for superior dependability.

Recognizing the special nature of space programs and the impact of component performance on system capability, we are fully prepared to provide either our standard S Level screening or full custom processing flows to suit your application requirements. Hybrid products can be processed to selected K (space) level criteria, but the final product would not be compliant or certified to MIL-STD-883 or MIL-M-38534, K level. Contact Comlinear for specific information.
Radiation testing has been completed on several Comlinear products at different levels. Our complementary bipolar IC process, for instance, has shown radiation tolerance up to one megarad total dose.

*Detail Reports Available*
Comlinear is involved in and supports a drawing (detail specification) standardization program administered by the Defense Electronics Supply Center (DESC). This program covers all Comlinear products compliant to MIL-STD-883 paragraph 1.2.1, MIL-M-38510 and MIL-H-38534 for monolithic and hybrid devices.

The following listing identifies those models which have DESC (SMD) approval or are in process. Comlinear will, upon device qualification, apply for and seek SMD approval of all products to be compliant to military standards.

Contact Comlinear for new releases or any models currently in-process which are not listed herein.

* Release Pending
This listing provides mean time between failure (MTBF) rate prediction analysis, calculated in accordance with MIL-HDBK-217E. The stated values are for MIL-STD-883, B level, H level, or Comlinear M level processed versions. For monolithic products, the number range of transistors has been shown; these products are achieving a continuous tested FIT (Failures in Time) rate of <1.0 fails per billion device hours.

\(^1\)Based on MIL-STD-883, B Level, H level or our M level versions; per MIL-HDBK-217E; Ground Fixed (GF) at 70° C case still air (hybrid), GF at 25° C ambient still air (monolithic).

\(^2\)For CLC hybrid products, the number of transistors is not listed due to further transistor attributes beyond the scope of this listing; these attributes should be discussed with Comlinear personnel directly.

\(^3\)H = hybrid; M = monolithic.

</tbody>
</table>

¹ Seal test (Subgroup 2B) need be performed only on packages that have leads exiting through a glass seal.

² Lid torque test shall apply only to packages which use a glass-frit-seal to lead frame lead or package body (i.e., wherever the frit seal establishes hermeticity or package integrity).

³ Microcircuits which are contained in packages which have an inner seal or cavity perimeter of two inches or more or have a package mass of 5 grams or more, may be tested to condition D (unless otherwise specified).

⁴ Adhesion of lead finish not applicable to leadless chip carriers.

A reliability qualification and monitoring program exists for all Hi-Rel as well as commercial/industrial products. Details of this program and current data for the different product lines are available upon request.

APPLICATIONS:
- coaxial line driving
- DAC current to voltage amplifier
- flash A to D driving
- baseband and video communications
- radar and IF processors

DESCRIPTION:
The CLC103 is a high-power, wideband op amp designed for the most demanding high-speed applications. The wide bandwidth, fast settling, linear phase, and very low harmonic distortion provide the designer with the signal fidelity needed in applications such as driving flash A to Ds. The 80MHz full-power bandwidth and 200mA output current of the CLC103 eliminate the need for power buffers in most applications; the CLC103 is an excellent choice for driving large high-speed signals into coaxial lines.

In the design of the CLC103 special care was taken in order to guarantee that the output settle quickly to within 0.4% of the final value for use with ultra fast flash A to D converters. This is one of the most demanding of all op amp requirements since settling time is affected by the op amp's bandwidth, passband gain flatness, and harmonic distortion. This high degree of performance ensures excellent performance in many other demanding applications as well.

The dynamic performance of the CLC103 is based on Comlinear's proprietary op amp topology. This new design provides performance far beyond that available from conventional op amp designs; unlike conventional op amps where optimum gain-bandwidth product occurs at a high gain, minimum settling time at a gain of −1, and maximum slew rate at a gain of +1, the Comlinear design provides consistent, predictable performance across its entire gain range. For example, the table below shows how the 3dB bandwidth remains nearly constant over a wide range of gains. And since the amplifier is inherently stable, no external compensation is required. The result is shorter design time and the ability to accommodate design changes (in gain, for example) without loss of performance or redesign of compensation circuits.

The CLC103 is constructed using thin film resistor/bipolar transistor technology. The CLC103AI is specified over a temperature range of −25°C to +85°C, while the CLC103AM is specified over a range of −55°C to +125°C and is screened to Comlinear's M Standard for high reliability applications. Both devices are packaged in 24-pin ceramic DIPs.

FEATURES:
- 80MHz full-power bandwidth (20Vpp, 100Ω)
- 200mA output current
- 0.4% settling in 10ns
- 6000V/μs slew rate
- 4ns rise and fall times (20V)

**FREQUENCY DOMAIN RESPONSE**

- 3dB bandwidth: \( V_{out} < 4V_{pp} \)
- gain flatness: \( V_{out} < 4V_{pp} \)
- peaking: 0.1 to 50MHz
- peaking: >50MHz
- rolloff: at 100MHz
- group delay: to 75MHz
- linear phase deviation: to 75MHz
- reverse isolation - non-inverting: to 150MHz

**TIME DOMAIN RESPONSE**

- rise and fall time: 5V step
- settling time to 0.4%: 10V step
- slew rate (overdriven input): 5V step
- overload recovery: 5ns pulse, 200% overdrive

**DISTORTION AND NOISE RESPONSE**

- 2nd harmonic distortion: \( 2V_{pp}, 20MHz \)
- 3rd harmonic distortion: \( 2V_{pp}, 20MHz \)
- equivalent input noise:
  - noise floor: >100kHz
  - integrated noise: 1kHz to 100MHz
  - integrated noise: 5MHz to 100MHz

**STATIC, DC PERFORMANCE**

- input offset voltage: 10
- input bias current:
  - non-inverting: 10
  - average temperature coefficient: 20
- input bias current:
  - inverting: 20
  - average temperature coefficient: 250
- power supply rejection ratio: 54
- common mode rejection ratio: 38
- supply current:
  - no load: 30

**MISCELLANEOUS PERFORMANCE**

- non-inverting input:
  - resistance: 250
  - capacitance: 2.4
- output impedance:
  - at DC: 4
  - at 100MHz: 2.45
- output voltage range: no load

- supply voltage (\( V_{cc} \)): ±20V
- output current: ±200mA
- thermal resistance (\( \theta_{ja} \)): see thermal model
- junction temperature: +175°C
- operating temperature:
  - Al: -25°C to +85°C
  - AM: -55°C to +125°C
- storage temperature: -65°C to +150°C
- lead temperature (soldering 10s): +300°C

**Note 1:** Parameters preceded by an * are the final electrical test parameters and are 100% tested. AM units are tested at -55°C, 25°C, and +125°C. AI units are tested only at +25°C although their performance is guaranteed at -25°C and +85°C as indicated above.

**Note 2:** This rating protects against damage to the input stage caused by saturation of either the input or output stages. Under transient conditions not exceeding 1μs (duty cycle not exceeding 10%, maximum input voltage may be as large as twice the maximum. \( V_{in} \) should never exceed ±5V. (\( V_{in} \) is the voltage at the non-inverting input, pin 7.)

**Note 3:** This rating protects against exceeding transistor collector-emitter breakdown ratings. Recommended \( V_{cc} \) is ±15V.
CLC103 Operation

The CLC103 is based on Comlinear's proprietary op amp topology, a unique design which uses current feedback instead of the usual voltage feedback. This design provides dynamic performance far beyond that previously available, yet it is used basically the same as the familiar voltage-feedback op amp (see the gain equations above). A complete discussion of current feedback is given in application note AN300-1.

Layout Considerations

To obtain optimum performance from any circuit operating at high frequencies, good PC layout is essential. Fortunately, the stable, well-behaved response of the CLC103 makes operation at high frequencies less sensitive to layout than is the case with other wideband op amps, even though the CLC103 has a much wider bandwidth.

In general, a good layout is one which minimizes the unwanted coupling of a signal between nodes in a circuit. A continuous ground plane from the signal input to output on the circuit side of the board is helpful. Traces should be kept short to minimize inductance. If long traces are needed, use microstrip transmission lines which are terminated in their characteristic impedance. At some high-impedance nodes, or in sensitive areas such as near pin 5 of the CLC103, stray capacitance should be kept small by keeping nodes small and removing ground plane directly around the node.

The ±Vcc connections to the CLC103 are internally bypassed to ground with 0.1μF capacitors to provide good high-frequency decoupling. It is recommended that 1μF or larger tantalum capacitors be provided for low-frequency decoupling. The 0.01μF capacitors shown at pins 18 and 20 in figures 1 and 2 should be kept within 0.1" of those pins. A wide strip of ground plane should be provided for a signal return path between the load-resistor ground and these capacitors.

Since the layout of the PC board forms such an important part of the circuit, much time can be saved if prototype amplifier boards are tested early in the design stage. Encased/connectorized amplifiers are available from Comlinear.

Settling Time, Offset, and Drift

After an output transition has occurred, the output settles very rapidly to the final value and no change occurs for several microseconds. Thereafter, thermal gradients inside the CLC103 will cause the output to begin to drift. When this cannot be tolerated, or when the initial offset voltage and drift is unacceptable, the use of a composite amplifier is advised.

A composite amplifier can also be referred to as a feed-forward amplifier. Most feed-forward techniques such as those used in the vast majority of wideband op amps, involve the use of a wideband AC-coupled channel in parallel with a low-bandwidth, high-gain DC-coupled amplifier. For the composite amplifier suggested for use with the CLC103, the CLC103 replaces the wideband AC-coupled amplifier and a low-cost monolithic op amp is used to supply high open-loop gain at low frequencies. Since the CLC103 is strictly DC coupled throughout, crossover distortion of less than 0.01dB and 1° results.

For composite operation in the non-inverting mode, the circuit in figure 1 should be modified by the addition of the circuit shown in figure 3. For inverting operation, modify the circuit in figure 2 by the addition of the circuit in figure 4. Keep all resistors which connect to the CLC103 within 0.2" of the CLC103 pins. The other side of these resistors should likewise be as close to U1 as possible. For good overall results, U1 should be similar to the LF356; this gives 5μV 3°C input offset drift and the crossover frequency occurs at about 2MHz. Since U1 has a feedback network composed of Rb + Rf and a 15kΩ resistor, which is in parallel with Rf and the internal 1.5kΩ feedback resistor of the CLC103, Rb must be adjusted to match the feedback ratios of the two networks. This is done by driving the composite amplifier with a 70kHz square wave large enough to produce a transition from +5V to −5V at the CLC103 output and adjusting Rb until the output of U1 is at a minimum. Rb should be about 9.5Rf for best results; thus, Rb should be adjusted around the value of 0.5Rf.

Bias Control

In normal operation, the bias control pin (pin 16) is left unconnected. However, if control over the bias of the amplifier is desired, the bias control pin may be driven with a TTL signal; a TTL high level will turn the amplifier off.

Distortion and Noise

The graphs of intercept point versus frequency on the preceding page make it easy to predict the distortion at any frequency, given the output voltage of the CLC103. First, convert the output voltage V20 to Vrms = (Vop/2√2) and then to P = (10log10[20(Vrms)2]) to get the output power in dBm. At the frequency of interest, its 2nd harmonic will be S2 = (I2−P)dB below the level of P. Its third harmonic will be S3 = 2(I2−P)dB below the level of P, as will the two-tone third order intermodulation products. These approximations are useful for $P < -1$ dB compression levels.

Approximate noise figure can be determined for the CLC103 using the Equivalent Input Noise graph on the preceding page. The following equation can be used to determine noise figure (F) in dB.

$$ F = 10\log\left[\frac{v_n^2 + i_n^2 R_f^2}{4 kT R_b M} + 1\right] $$

where $v_n$ is the rms noise voltage and $i_n$ is the rms noise current. Beyond the breakpoint of the curve (i.e., where they are flat), broadband noise figure equals spot noise, so $M$ should equal one (1) and $v_n$ and $i_n$ should be read directly off the graph. Below the breakpoint, the noise must be integrated and $M$ set to the appropriate bandwidth.

Application Notes and Assistance

Application notes that address topics such as data conversion, fiber optics, and general high-frequency circuit design are available from Comlinear or your Comlinear sales engineer.

Comlinear maintains a staff of highly-qualified applications engineers to provide technical and design assistance.
APPLIICATIONS:
• fast, precision A to D, D to A conversion
• baseband and video communications
• radar, sonar, IF processors
• laser drivers, photodiode preamps
• graphic CRT composite video drive amp

DESCRIPTION:
The CLC200 operational amplifier achieves performance far superior to that of other high performance op amps. A proprietary Comlinear design provides a bandwidth of DC-95MHz and an unprecedented settling time of 18ns to 0.1%. And since thermal tail has been eliminated, the CLC200 can be depended upon to settle fast and solidly maintain its level. Drive capability is also impressive at 24Vpp and 100mA.

Using the CLC200 is as easy as adding power supplies and a gain-setting resistor. The result is reliable, consistent performance because such characteristics as bandwidth and settling time are virtually independent of gain setting. Unlike conventional op amp designs where the optimum gain-bandwidth product occurs at a high gain, minimum settling time at a gain of -1, maximum slew rate at a gain of +1, et cetera, the CLC200 offers predictable response at gain settings from ±1 to ±50. This, coupled with consistent performance from unit to unit with no external compensation, makes the CLC200 a real time and cost-saver in design and production situations alike.

Minimizing settling time was a design goal of the CLC200. Settling time is one of the most demanding of all op amp requirements since it is affected by the op amp’s bandwidth, gain flatness, and harmonic distortion. The result of this effort is an amplifier fast enough for the most demanding high speed D to A converters and “flash” A to D converters.

The superior slew rate and rise and fall times of the CLC200 make it an ideal amplifier for a broad range of pulse, analog, and digital applications. Flat gain and phase response from DC to beyond 50MHz ensure distortion levels well below those of other op amps. A full power bandwidth of 20MHz eliminates the need for power buffers in many applications.

The CLC200 is constructed using thin film resistor/bipolar transistor technology. The CLC200A1 is specified over a temperature range of -25°C to +85°C, while the CLC200A8C is specified over a range of -55°C to +125°C and is fully compliant with MIL-STD-883, Level B. Both devices are packaged in 12-pin metal TO-8 cans. The DESC SMD number is 5962-89910.

- Common mode rejection ratio: \( <40\) dB, \( <40\) dB, \( <40\) dB
- Supply current: \( <36\) mA, \( <34\) mA, \( <36\) mA

**MISCELLANEOUS PERFORMANCE**
- Non-inverting input resistance: \( >250\) kΩ, \( >100\) kΩ, \( >100\) kΩ
- Capacitance: \( 2.4\) pF, \( <3\) pF, \( <3\) pF
- Output impedance at DC: \( -0.1\) Ω, \( -0.1\) Ω, \( -0.1\) Ω
- Output impedance at 50MHz: \( 1.35\) Ω, \( 1.35\) Ω, \( 1.35\) Ω
- Output voltage range: \( ±12\) V, \( ±11\) V, \( ±11\) V
- Internal feedback resistor: \( <0.4\) %, \( <0.4\) %, \( <0.4\) %

**Absolute Maximum Ratings**
- Supply voltage: \( ±20\) V
- Output current: \( ±100\) mA
- Thermal resistance (\( R_{th}\)): see thermal model
- Junction temperature: \( +175\) °C
- Operating temperature: \( A1: -25\) °C to \( +85\) °C, \( A2: -55\) °C to \( +125\) °C
- Storage temperature: \( -65\) °C to \( +150\) °C
- Lead temperature (soldering 10s): \( +300\) °C

**Notes:**
1. Parameters preceded by an * are the final electrical test parameters and are 100% tested. All units are tested at -25°C, +25°C, and +125°C. All units are tested only at +25°C although performance at -25°C and +85°C is guaranteed to be better than or equal to the performance specified for A8 devices in the -55°C and +125°C ranges. Maximum temperature coefficient parameters apply only to A8 devices.
2. This rating protects against damage to the input stage caused by saturation of either the input or output stages. Under transient conditions not exceeding 1μs (duty cycle not exceeding 10%), maximum input voltage may be as large as twice the maximum. \( V_{in}\) should never exceed \( V_{cc}\) (\( V_{in}\) is the voltage at the non-inverting input, pin 6).
3. This rating protects against exceeding transistor collector-emitter breakdown ratings. Recommended \( V_{cc}\) is \( ±15\) V.
4. Settling time specifications require the use of an external feedback resistor (20kΩ).
Controlling Bandwidth and Passband Response

As with any op amp, the ratio of the two feedback resistors $R_1$ and $R_2$ determines the gain of the CLC200. Unlike conventional op amps, however, the closed loop pole-zero response of the CLC200 is affected very little by the value of $R_1$, $R_2$ scales the magnitude of the gain, but does not change the value of the feedback. This is possible due to a proprietary circuit topology. $R_1$ does influence the feedback and so the CLC200 has been internally compensated for optimum performance with $R_1 = 2000\Omega$, but any value of $R_1 \geq 1k\Omega$ may be used with a single capacitor placed between pins 4 and 5 for compensation. See Table 1. As $R_1$ decreases, $C_e$ must increase to maintain flat gain. Slew rate will decrease slightly with increasing $C_e$, but other parameters such as bandwidth, settling time, and phase linearity will improve. Large values of $R_1$ and $C_e$ can be used together or separately to reduce the bandwidth. This may be desirable for reducing the bandwidth in applications not requiring the full frequency response available although this may cause the output noise to increase at low gains.

Layout Considerations

To assure optimum performance the user should follow good layout practices which minimize the unwanted coupling of signals between nodes. During initial breadboarding of the circuit, use direct point to point wiring, keeping the lead lengths to less than 25". The use of solid, unbroken ground plane is helpful. Avoid wire-wrap type pc boards and methods. Sockets with small, short pin receptacles may be used with minimal performance degradation although their use is not recommended.

During pc board layout, keep all traces short and direct. The resistive body of $R_3$ should be as close as possible to pin 5 to minimize capacitance at that point. For the same reason, remove ground plane from the vicinity of pins 5 and 6. In other areas, use as much ground plane as possible on one side of the board. It is especially important to provide a ground return path for current from the load resistor to the power supply bypass capacitors. Ceramic capacitors of .01 to .1μF (with short leads) should be less than .15 inches from pins 1 and 9. Larger tantalum capacitors should be placed within one inch of these pins. $V_{cc}$ connections to pins 10 and 12 can be made directly from pins 9 and 1, but better supply rejection and settling time are obtained if they are separately bypassed as in Figures 1 and 2. To prevent signal distortion caused by reflections from impedance mismatches, use terminated microstrip of coaxial cable when the signal must traverse more than a few inches.

Since the pc board forms such an important part of the circuit, much time can be saved if prototype boards of any high frequency sections are built and tested early in the design phase. Evaluation boards designed for either inverting or non-inverting gains are available from Comlinear at minimal cost.

Distortion and Amplification Fidelity

The graphs of intercept point versus frequency on the preceding page make it easy to predict the distortion at any frequency, given the output voltage of the CLC200. First, convert the output voltage ($V_O$ to $V_{rms} = (V_{pp}/\sqrt{2})$ and then to $P = (10\log_{10}(20V_{rms}))^2$ to get output power in dBm. At the frequency of interest, its 2nd harmonic will be $S_2 = (I_0 - P) dB$ below the level of $P$. Its third harmonic will be $S_3 = (I_0 - P) dB$ below $P$, as will the two-tone third order intermodulation products. These approximations are useful for $P < -1$ dB compression levels.

Approximate noise figure can be determined for the CLC200 using the Equivalent Input Noise graph on the preceding page. The following equation can be used to determine noise figure (F) in dB.

$$F = 10 \log \left( 1 + \frac{v_n}{v_i + 2(10R_s R_n)^{1/2}} \right)$$

where $v_i$ is the rms noise voltage and $v_n$ is the rms noise current at the inverting node. Beyond the breakpoint of the curves (i.e., where they are flat), broadband noise figure equals spot noise figure, so $\Delta f$ should equal one (1) and $v_i$ and $v_n$ should be read directly off the graph. Below the breakpoint, the noise must be integrated and $\Delta f$ set to the appropriate bandwidth.

For linear operation of the CLC200 at large output voltage swings (DC component not included) and at high frequencies, observe the (AC output voltage) × (frequency) product specification of 400V × MHz. Exceeding this rating will cause the signal to be greatly distorted as the amplifier bias control circuit reduces the current available for slewing to prevent damage. At frequencies and voltages within this range the excess slewing rate and bandwidth available will ensure the highest possible degree of amplified signal fidelity.

Operation with Reduced Bias Current

Placing a resistor between pins 1 and 2 will cause the CLC200 bias current to be reduced. A value of 20kΩ will cause only a slight reduction, 3kΩ will almost halve the current, while less than 1kΩ will reduce bias to about 5mA and the amplifier will be off. In this condition, the input signal will be greatly attenuated. In the reduced bias, on condition, bandwidth will be roughly proportional to the reduction in bias current. A mechanical or semiconductor switch can be used to turn the amplifier off. Any connection which would cause current to flow out of pin 2 will result in increased bias current and may lead to device destruction from overheating and excessive current.

Thermal Considerations

At high ambient temperatures or large internal power dissipations, heat sinking is required to maintain acceptable junction temperatures. Use the thermal model on the previous page to determine junction temperatures. Many styles of heat sinks are available for TO-8 packages; the Thermallyloy 2240 and 2268 are good examples. Some heat sinks are the radial fin type which cover the pc board and may interfere with external components. An excellent solution to this problem is to use surface mounted resistors and capacitors. They have a very low profile and actually improve high frequency performance. For use of these heat sinks with conventional components, a 1” high spacer can be inserted under the TO-8 package to allow sufficient clearance.

Application Notes and Assistance

Application notes that address topics such as data conversion, fiber optics, and general high frequency circuit design are available from Comlinear or your Comlinear sales engineer.

Comlinear maintains a staff of highly qualified applications engineers to provide technical and design assistance.
APPLICATIONS:
- fast, precision A to D, D to A conversion
- baseband and video communications
- radar, sonar, IF processors
- laser drivers, photodiode preamps
- graphic CRT composite video drive amp
- high resolution imaging systems

DESCRIPTION:
The CLC201 is a wideband operational amplifier that combines state of the art dynamic performance with excellent DC performance. This combination allows designers to maximize system performance without making the speed versus DC accuracy compromises that are necessary with most high-speed amplifiers. For example, the CLC201 provides a -3dB bandwidth of 95MHz (at a gain of +20) and a settling time of only 18ns (to 0.1%) yet exhibits an input offset voltage that is typically only 0.5mV and guaranteed to be less than 1.0mV at +25°C. The input offset voltage drift is typically only 5pV/°C.

The superior slew rate and rise and fall times of the CLC201 make it an ideal amplifier for a broad range of pulse, analog, and digital applications. The full-power bandwidth of 50MHz and 100mA output current eliminate the need for power buffers in most applications. Flat gain and phase response from DC to beyond 50MHz ensure distortion levels well below those of other op amps; in high-resolution applications such as 12-bit A to D converters, this low distortion combined with the excellent DC performance allows maximum accuracy and dynamic range—without the need for complicated error correction circuitry. Engineers desiring to increase the DC performance or full-power bandwidth of systems using the original CLC200 may replace it with a CLC201—in most cases with no design changes (they are pin compatible, however the CLC201 has neither a bias control pin nor a compensation pin).

The excellent dynamic performance is due to Comlinear's proprietary op amp topology, a unique design which is not subject to the limitations of the conventional op amp design. Dynamic parameters such as settling time and bandwidth are virtually independent of gain; for example, at a gain of -4, the bandwidth is 105MHz, yet it is still 95MHz at a gain of -20 (see the table below). In addition, the CLC201 is inherently stable across its entire (±1 to ±50) gain range. Besides the performance, the benefit of these features is reduced design time and the ability to make design changes with little or no change in dynamic performance.

The CLC201 is constructed using thin film resistor/bipolar transistor technology. The CLC201A1 is specified over a temperature range of -25°C to +85°C, while the CLC201A8C is specified over a range of -55°C to +125°C and is fully compliant with MIL-STD-883 Level B. Both devices are packaged in 12-pin metal TO-8 cans. The DESC SMD number is 5962-90833.

FEATURES (typical):
- -3dB bandwidth of 95MHz
- 0.5mV input offset voltage, 5pV/°C drift
- 0.1% settling in 18ns
- 4000V/μs slew rate
- 3.6ns rise and fall times

#### MISCELLANEOUS PERFORMANCE
- non-inverting input resistance: 250 kΩ >100 kΩ >100 kΩ kΩ RIN
- capacitance: 2.4 pF <3 pF <3 pF pF CIN
- output impedance: 1.35 Ω <0.1 Ω <0.1 Ω Ω RO
- output voltage range: ±12 V >11 V >11 V V VO
- internal tolerance: <0.4 % % % % RFA

### Absolute Maximum Ratings

#### Common Mode and Output Voltage Limits

- Supply voltage ($V_{CC}$)$=\pm 20V$
- Output current: ±100mA
- Thermal resistance ($\theta_{ja}$) see thermal model
- Junction temperature: 175°C
- Operating temperature: 25°C to +85°C
- Storage temperature: -65°C to +150°C
- Lead temperature (soldering 10s): +300°C

*note 1: Parameters preceded by an * are the final electrical test parameters and are 100% tested. All units are tested at -55°C, +25°C, and +125°C. All units are tested at +25°C although performance at -25°C and +85°C is guaranteed at -25°C and +85°C as indicated above.

*note 2: This rating protects against damage to the input stage caused by saturation of either the input or output stages. Under transient conditions not exceeding 1μs (duty cycle not exceeding 10%), maximum input voltage may be as large as twice the maximum. $V_{CC}$ should never exceed $V_{KB}$ ($V_{CC}$ is the voltage at the non-inverting input, pin 8).

*note 3: This rating protects against exceeding transistor collector-emitter breakdown ratings. Recommended $V_{CC}$ is ±15V.

*note 4: Settling time specifications require the use of an external feedback resistor (200Ω).

Continental reserves the right to change specifications without notice.

15°C/W in 300ft/min air with a Thermalloy 2268

$T_{j}(pnp) = P_{pnp} (32 + (T_{a} + 273))$ similar for $T_{j}(nnp)$.
CLC201 Operation

The CLC201 is based on Comlinear's proprietary op amp topology, a unique design that uses current feedback instead of the usual voltage feedback. This design provides dynamic performance far beyond that previously available, yet it is used basically the same as the familiar voltage-feedback op amp (see the gain equations above). A complete discussion of current feedback is given in application note AN300-1.

Controlling Bandwidth and Passband Response

In most applications, use of the internal 20000 feedback resistor will provide optimum dynamic performance; nonetheless, some designs may require an external feedback resistor of some value other than 20000Ω. The table below shows how bandwidth depends on the value of RI. Values of feedback resistance greater than 20000Ω will decrease the bandwidth of the amplifier; values of RI less than 20000Ω will increase the bandwidth. At most gain settings, however, low values of RI may cause instability unless a small amount of compensation capacitance (typically <0.5pF) is connected in parallel with RI. At |A| <, RI must be greater than 1kΩ.

<table>
<thead>
<tr>
<th>RI (external)</th>
<th>Bandwidth (dB)</th>

<td>90MHz</td>
</tr>
<tr>
<td>5kΩ</td>
<td>30MHz</td>
</tr>
<tr>
<td>10kΩ</td>
<td>15MHz</td>
</tr>
</tbody>
</table>

At large closed-loop gains (|A| > 50) the bandwidth may be increased by using a low value of RI as the table below indicates. External compensation is not required under these high-gain conditions.

Layout Considerations

To assure optimum performance the user should follow good layout practices which minimize the unwanted coupling of signals between nodes. During initial breadboarding of the circuit, use direct point to point wiring, keeping the lead lengths to less than 25". The use of solid, unbroken ground plane is helpful. Avoid wire-wrap type pc boards and methods. Sockets with small, short pin receptacles may be used with minimal performance degradation although their use is not recommended.

During pc board layout, keep all traces short and direct. The resistive body of Rg should be as close as possible to pin 5 to minimize capacitance at that point. For the same reason, remove ground plane from the vicinity of pins 5 and 6. In other areas, use as much ground plane as possible on one side of the board. It is especially important to provide a ground return path for current from the load resistor to the power supply bypass capacitors. Ceramic capacitors of .01 to .1μF (with short leads) should be less than .15 inches from pins 9 and 1. Larger tantalum capacitors should be placed within one inch of these pins. Vcc connections to pins 10 and 12 can be made directly from pins 9 and 1, but better supply rejection and settling time are obtained if they are separately bypassed as in Figures 1 and 2. To prevent signal distortion caused by reflections from impedance mismatches, use terminated microstrip or coaxial cable when the signal must traverse more than a few inches.

Distortion, Noise, and Amplification Fidelity

The graphs of intercept point versus frequency on the preceding page make it easy to predict the distortion at any frequency, given the output voltage of the CLC201. First, convert the output voltage (Vs) to VPMS = (Vpp/2√2) and then to P = (10log10(20VPM2)) to get output power in dBm. At the frequency of interest, its 2nd harmonic will be S2 = (2β−P)dB below the level of P; its third harmonic will be S3 = 2l(β−P)dB below P, as will the two-tone third order intermodulation products. These approximations are useful for P<−1 dB compression levels.

Approximate noise figure can be determined for the CLC201 using the Equivalent Input Noise graph on the preceding page. The following equation can be used to determine noise figure (F) in dB.

\[
F = 10 \log \left( \frac{v_n^2 + \frac{I_n^2}{R_s^2} + \frac{I_n^2}{R_t^2}}{4kT R_s \Delta f} \right)
\]

where \(v_n\) is the rms noise voltage and \(I_n\) is the rms noise current at the inverting node. Beyond the breakpoint of the curves (i.e., where they are flat), broadband noise figure equals spot noise figure, so \(\Delta f\) should equal one (1) and \(v_n\) and \(I_n\) should be read directly off the graph. Below the breakpoint, the noise must be integrated and \(\Delta f\) set to the appropriate bandwidth.

For linear operation of the CLC201 at large output voltage swings (DC component not included) and at high frequencies, limit the (AC output voltage) × (frequency) product to 1000V-MHz. Exceeding this rating will cause the signal to be greatly distorted as the amplifier bias control circuit reduces the current available for slewing to prevent damage. At frequencies and voltages within this range the excess slew rate and bandwidth available will ensure the highest possible degree of amplified signal fidelity.

Thermal Considerations

At high ambient temperatures or large internal power dissipations, heat sinking is required to maintain acceptable junction temperatures. Use the thermal model on the previous page to determine junction temperatures. Many styles of heat sinks are available for TO-8 packages; the Thermalley 2240 and 2268 are good examples. Some heat sinks are the radial fin type which cover the pc board and may interfere with external components. An excellent solution to this problem is to use surface mounted resistors and capacitors. They have a very low profile and actually improve high frequency performance. For use of these heat sinks with conventional components, a 0.1” high spacer can be inserted under the TO-8 package to allow sufficient clearance.

Application Notes and Assistance

Application notes that address topics such as data conversion, fiber optics, and general high frequency circuit design are available from Comlinear or your Comlinear sales engineer.

Comlinear maintains a staff of highly qualified application engineers to provide technical and design assistance.
APPLICATIONS:
- coaxial line driving
- DAC current to voltage amplifier
- flash A to D driving
- baseband and video communications
- radar and IF processors

DESCRIPTION:
The CLC203 is a wideband, high-current operational amplifier which features a unique combination of high power and high precision. The amplifier's output current of 200mA and a full-power bandwidth of 60MHz (20Vpp, 100Ω) ensure a quick design solution for the most demanding loads and signals. The solid 15ns settling time (to 0.2%) is reinforced by the CLC203's excellent DC performance; typically, the input offset voltage is only 0.5mV and is guaranteed to be less than 1mV at +25°C. The input offset voltage drift is typically only 5μV/°C.

The CLC203 is well suited to a wide range of applications. Specifically, the wide bandwidth, fast settling, linear phase, and very low harmonic distortion provide the designer with the signal fidelity needed in applications such as driving flash A to Ds or coaxial lines. The 60MHz full-power bandwidth and 200mA output current of the CLC203 eliminate the need for power buffers in most applications. Engineers desiring to improve the DC performance or settling precision of systems using the original CLC103 may replace it with a CLC203-in most cases with no design changes (they are pin compatible, however the CLC203 does not have a bias control pin).

The dynamic performance of the CLC203 is based on Comlinear's proprietary op amp topology. This new design provides performance far beyond that available from conventional op amp designs; for example, the -3dB bandwidth remains nearly constant over a wide range of gains. (See the table below.) And since the amplifier is inherently stable, the user is saved the trouble and expense of designing external compensation networks. The result is shorter design time and the ability to accommodate design changes (in gain, for example) without loss of performance or a redesign of compensation circuits.

The CLC203 is constructed using thin film resistor/bipolar transistor technology. The CLC203AI is specified over a temperature range of -25°C to +85°C, while the CLC203AM is specified over a range of -55°C to +125°C and is screened to Comlinear's M Standard for high reliability applications. Both devices are packaged in 24-pin ceramic DIPs.

FEATURES:
- 60MHz full-power bandwidth (20Vpp, 100Ω)
- 200mA output current
- 0.2% settling in 15ns
- 0.5mV input offset voltage, 5μW/°C drift
- 4ns rise and fall times (20V)

**Common Mode and Output Voltage Limits**

Supply voltage ($V_{cc}$): ±20V
Output current: ±200mA
Thermal resistance ($\theta_{ja}$): see thermal model
Junction Temperature: +175°C
Operating Temperature
- AM: −55°C to +125°C
- AM: −85°C to +125°C
Storage Temperature: −65°C to +150°C
Lead Temperature (soldering 10s): +300°C

*Note 1:* Parameters preceded by an * are the final electrical test parameters and are 100% tested. AM units are tested at −55°C, +25°C, and +125°C. Al units are tested only at +25°C although their performance is guaranteed at −25°C and +85°C as indicated above.

*Note 2:* This rating protects against damage to the input stage caused by saturation of either the input or output stages. Under transient conditions not exceeding 1µs (duty cycle not exceeding 10%), maximum input voltage may be as large as twice the maximum. $V_{em}$ should never exceed $V_{cc}$. ($V_{em}$ is the voltage at the non-inverting input, pin 7.)

*Note 3:* This rating protects against exceeding transistor collector-emitter breakdown ratings. Recommended $V_{cc}$ is ±15V.

Comlinear reserves the right to change specifications without notice.
CLC203 Operation

The CLC203 is based on Comlinear's proprietary op amp topology, a unique design which uses current feedback instead of the usual voltage feedback. This design provides dynamic performance far beyond that previously available, yet it is used basically the same as the familiar voltage-feedback op amp (see the gain equations above). A complete discussion of current feedback is given in application note AN300-1.

Increasing Bandwidth at High Gains

At high gains ($|A_v| \geq 50$) the bandwidth of the CLC203 may be increased by lowering the value of feedback resistance. This is done by connecting an external resistor in parallel with the internal 1500$\Omega$ feedback resistor. The table below shows the recommended external resistor values for different gain settings.

| $|A_v|$ | external resistor | $-3$dB bandwidth |
|-------|-----------------|-----------------|
| 50    | 3k$\Omega$      | 140MHz          |
| 100   | 750$\Omega$     | 110MHz          |

Layout Considerations

To obtain optimum performance from any circuit operating at high frequencies, good PC layout is essential. Fortunately, the stable, well-behaved response of the CLC203 makes operation at high frequencies less sensitive to layout than is the case with other wideband op amps, even though the CLC203 has a much wider bandwidth.

In general, a good layout is one which minimizes the unwanted coupling of a signal between nodes in a circuit. A continuous ground plane from the signal input to output on the circuit side of the board is helpful. Traces should be kept short to minimize inductance. If long traces are needed, use microstrip transmission lines which are terminated in their characteristic impedance. At some high-impedance nodes, or in sensitive areas such as near pin 5 of the CLC203, stray capacitance should be kept small by keeping nodes small and removing ground plane directly around the node.

The $\pm V_{cc}$ connections to the CLC203 are internally bypassed to ground with 0.022$\mu$F capacitors to provide good high-frequency decoupling. It is recommended that 1$\mu$F or larger tantalum capacitors be provided for low-frequency decoupling. The 0.01$\mu$F capacitors shown at pins 18 and 20 in figures 1 and 2 should be kept within 0.1” of those pins. A wide strip of ground plane should be provided for a signal return path between the load-resistor ground and these capacitors.

Since the layout of the PC board forms such an important part of the circuit, much time can be saved if prototype amplifier boards are tested early in the design stage. Encased/connectorized amplifiers are available from Comlinear.

Distortion and Noise

The graphs of intercept point versus frequency on the preceding page make it easy to predict the distortion at any frequency, given the output voltage of the CLC203. First, convert the output voltage ($V_0$) to $V_{rm}$ = ($V_{pp} / 2\sqrt{2}$) and then to $P$ = (10log($20V_{rm^2}$)) to get the output power in dBm. At the frequency of interest, its 2nd harmonic will be $S_2$ = (1$\frac{2}{P}$)dB below the level of $P$. Its third harmonic will be $S_3$ = 2(|$I_3$|−$P$)dB below the level of $P$, as will the two-tone third order intermodulation products. These approximations are useful for $P$ < -1 dB compression levels.

Approximate noise figure can be determined for the CLC203 using the Equivalent Input Noise graph on the preceding page. The following equation can be used to determine noise figure ($F$) in dB.

$$F = 10\log\left[1 + \frac{v_n^2 + i_n^2 R_n^2}{A^2} \frac{R_s^2}{4kT\Delta f}\right]$$

where $v_n$ is the rms noise voltage and $i_n$ is the rms noise current at the inverting node. Beyond the breakpoint of the curves (i.e., where they are flat), broadband noise figure equals spot noise, so $\Delta f$ should equal one (1) and $v_n$ and $i_n$ should be read directly off the graph. Below the breakpoint, the noise must be integrated and $\Delta f$ set to the appropriate bandwidth.

Application Notes and Assistance

Application notes that address topics such as data conversion, fiber optics, and general high-frequency circuit design are available from Comlinear or your Comlinear sales engineer.

Comlinear maintains a staff of highly-qualified applications engineers to provide technical and design assistance.
APPLICATIONS:

• high-speed modems, radios
• line drivers

DESCRIPTION:
The CLC205 is a wideband overdrive-protected operational amplifier designed for applications needing both speed and low power operation. Utilizing Comlinear’s well-established current feedback architecture, the CLC205 exhibits performance far beyond that of conventional voltage feedback op amps. For example, the CLC205 has a bandwidth of 170MHz at a gain of +20 and settles to 0.1% in 22ns. Plus, the CLC205 has a combination of important features not found in other high-speed op amps.

For example, the CLC205 has been designed to consume little power—570mW at ±15V supplies. The result is lower power supply requirements and less system-level heat dissipation. In addition, the device can be operated on supply voltages as low as ±5V for even lower power dissipation.

Complete overdrive protection has been designed into the part. This is critical for applications, such as ATE and instrumentation, which require protection from signal levels high enough to cause saturation of the amplifier. This feature allows the output of the op amp to be protected against short circuits using techniques developed for low-speed op amps. With this capability, even the fastest signal sources can feature effective short circuit protection.

The CLC205 is constructed using thin-film resistor/bipolar transistor technology and is available in three versions. The CLC205AI is specified over a temperature range of −25°C to +85°C. The CLC205AK, which features burn in and tested hermeticity, is specified and tested over a temperature range of −55°C to +125°C. The CLC205A8C is specified and tested over a temperature range of −55°C to +125°C and is fully compliant with MIL-STD-883, Level B. All three versions are packaged in 12-pin TO-8 cans. The DESC SMD number is 5962-90835.

FEATURES:
• −3dB bandwidth of 170MHz
• 0.1% settling in 22ns
• complete overdrive protection
• low power: 570mW (57mW at ± 5V)
• 3MΩ input resistance
• output may be current limited

**note:** 1: Parameters preceded by an * are 100% tested. A6 and AK units are tested at -55°C, +25°C, and +125°C. AI units tested at +25°C, although performance at -25°C and +85°C is guaranteed as shown above.

**note:** 2: Setting time specifications require the use of an external feedback resistor (2Ω).

**note:** 3: In AI units, the noise and distortion specifications are guaranteed (but not tested) as shown above.

Comlinear reserves the right to change specifications without notice.

3 – 24
Non-Inverting Gain and Phase

Gain

$A_\text{v} = +7$

$A_\text{v} = +50$  $A_\text{v} = +20$

Phase

$A_\text{v} = -7$

$A_\text{v} = -50$  $A_\text{v} = -20$

Frequency (Hz)

0 20MHz/div 200MHz

Large Signal Gain and Phase

Gain

$V_\text{dc} = 10V_{\text{dc}}$

Phase

$V_\text{dc} = 24V_{\text{dc}}$

$V_\text{dc} = 20V_{\text{dc}}$

Small Signal Pulse Response

$A_\text{v} = +20$

$A_\text{v} = -20$

$P_{\text{trans}} = [(V_{\text{cc}} + 1.77k\Omega) / 3mA, \text{whichever is greater. (Include feedback resistance in R in R_{\text{f}})}}$

$P_{\text{trans}} = [(\pm V_{\text{cc}} - (V_{\text{ce}} - (1.77k\Omega) / 3mA)]$ (\% duty cycle)

2nd and 3rd Harmonic Distortion

2-Tone 3rd Order Intermodulation Intercept

CMRR and PSRR

Thermal Model

$\theta = 65^\circ\text{C}/\text{W}$ in still air without a heat sink

$35^\circ\text{C}/\text{W}$ in still air with a Thermallyloy 2240

$15^\circ\text{C}/\text{W}$ in 300 ft/min air with a Thermallyloy 2268 (Thermallyloy 2240 works equally well.)

$R_{\text{f}} = (P_{\text{trans}} + \theta_{\text{t}}) / T_{\text{t}}$

$T_{\text{t}} = R_{\text{f}} / T_{\text{t}}$

$T_{\text{t}} = R_{\text{f}} / (R_{\text{f}} + \theta_{\text{t}})$ similar for $T_{\text{t}}$

$R_{\text{f}}$ is a resistor (330 ohm recommended) between the xxx collector and $\pm V_{\text{cc}}$.
**Overdrive Protection**

Unlike most other high-speed op amps, the CLC205 is not damaged by saturation caused by overdriving input signals (where \( V_{in} \times \text{gain} > \max. V_{sat} \)). The CLC205 self limits the current at the inverting input when the output is saturated (see the inverting input current self limit specification); this ensures that the amplifier will not be damaged due to excessive internal currents during overdrive. For protection against input signals which would exceed either the maximum differential or common mode input voltage, the diode clamp circuits below may be used.

![Diode clamp circuits for common mode and differential mode protection](image)

**Short Circuit Protection**

Damage caused by short circuits at the output may be prevented by limiting the output current to safe levels. The most simple current limit circuit calls for placing resistors between the output stage collector supplies and the output stage collectors (pins 12 and 10). The value of this resistor is determined by:

\[
R_c = \frac{V_c}{I_i} - R_i
\]

Where \( I_i \) is the desired limit current and \( R_i \) is the minimum expected load resistance (0Ω for a short to ground). Bypass capacitors of 0.01µF on should be used on the collectors as in Figures 1 and 2.

A more sophisticated current limit circuit which provides a limit current independent of \( R_i \) is shown below.

![Active current limit circuit (50mA)](image)

**Contrasting Bandwidth and Passband Response**

In most applications, a feedback resistor value of 2kΩ will provide optimum performance; nonetheless, some applications may require a resistor of some other value. The response versus \( R_f \) plot on the previous page shows how decreasing \( R_f \) will increase bandwidth (and frequency response peaking, which may lead to instability). Conversely, large values of feedback resistance tend to roll off the response.

The best settling time performance requires the use of an external feedback resistor (use of the internal resistor results in a 0.1% to 0.2% settling tail). The settling performance may be improved slightly by adding a capacitance of 0.4pF in parallel with the feedback resistor (setting time specifications reflect performance with an external feedback resistor but with no external capacitance).

**Noise Analysis**

Approximate noise figure can be determined for the CLC205 using the equivalent input noise graph on the preceding page and the equations shown below.

\[
F = 10\log \left[ 1 + \frac{R_s}{R_n} + \frac{R_s}{4kT} \left( \frac{i_n^2 + V_n^2}{R_p^2} + \frac{i_n^2}{R_p^2 A_v^2} \right) \right]
\]

where \( R_p = \frac{R_s}{R_n} \); \( A_v = \frac{R_f}{R_a} + 1 \)

\( kT = 4.00 \times 10^{-21} \) Joules at 290°C

\( V_n \) is spot noise voltage (V / √Hz)

\( i_n \) is non-inverting spot noise current (A / √Hz)

\( i_i \) is inverting spot noise current (A / √Hz)

**Printed Circuit Layout**

As with any high frequency device, a good PCB layout will enhance the performance of the CLC205. Good ground plane construction and power supply bypassing close to the package are critical to achieving full performance. In the non-inverting configuration, the amplifier is sensitive to stray capacitance to ground at the inverting input. Hence, the inverting node connections should be small with minimal stray capacitance to the ground plane or other nodes. Shunt capacitance across the feedback resistor should not be used to compensate for this effect.

Evaluation PC boards (part number 730008 for inverting, 730009 for non-inverting) for the CLC205 are available.

- input/output amplifiers
- photodiode, CCD preamps
- IF processors
- high-speed modems, radios
- line drivers

DESCRIPTION:
The CLC206 is a wideband, overdrive-protected operational amplifier designed for applications needing both speed and high drive capability (100mA). Utilizing Comlinear's well-established current feedback architecture, the CLC206 exhibits performance far beyond that of conventional voltage feedback op amps. For example, the CLC206 has a bandwidth of 180MHz at a gain of +20 and settles to 0.1% in 19ns. Plus, the CLC206 has a combination of important features not found in other high-speed op amps.

The 100mA output current and the large signal bandwidth of 70MHz (20Vpp) make the CLC206 ideal for applications which involve both high signal amplitudes and heavy loads as in coaxial line driving applications.

Complete overdrive protection has been designed into the CLC206. This is critical for applications, such as ATE and instrumentation, which require protection from signal levels high enough to cause saturation of the amplifier. This feature allows the output of the op amp to be protected against short circuits using techniques developed for low-speed op amps. With this capability, even the fastest signal sources can feature effective short circuit protection.

The CLC206 is constructed using thin-film resistor/bipolar transistor technology and is available in three versions. The CLC206A1 is specified over a temperature range of -25°C to +85°C. The CLC206AK, which features burn in and tested hermeticity, is specified and tested over a temperature range of -55°C to +125°C. The CLC206A8C is specified and tested over a temperature range of -55°C to +125°C and is fully compliant with MIL-STD-883, Level B. All three versions are packaged in 12-pin TO-8 cans. The DESC SMD number is 5962-89858.

FEATURES:
- −3dB bandwidth of 180MHz
- 70MHz large signal bandwidth (20Vpp)
- 0.1% settling in 19ns
- overdrive protected
- output may be current limited
- stable w/o compensation
- 3MΩ input impedance

Thermal Model

Noise Voltage (mV/\( V_{cc} \))

Inverting Current 19.6 pA/\( V_{cc} \)

Non-Inverting Current 2.7 pA/\( V_{cc} \)

Voltage 1.9 mV/\( V_{cc} \)

\( R_{in} \) = 65°C/W in still air without a heatsink
35°C/W in still air with a Thermatloy 2268
15°C/W in 300ft/min air with a Thermatloy 2268
(Thermatloy 2240 works equally well.)
Figure 4: Active current limit circuit (100mA)

With the component values indicated, current limiting occurs at 100mA. For other values of current limit (Ii), select \( R_i \) to equal \( V_{be}/I_i \). Where \( V_{be} \) is the base to emitter voltage drop of Q3 (or Q4) at a current of \( [2V_{cc} - 1.4]/R_i \), where

\[ R_i \leq \frac{[2V_{cc} - 1.4]}{I_i} \]

where \( R_i \) is the minimum beta of Q1 (or Q2). Also, \( B_{min} \) is the minimum beta of Q1 (or Q2) at a current of \( I_i \). Since the limit current depends on \( V_{be} \), which is temperature dependent, the limit current is likewise temperature dependent. If a temperature-independent current limit circuit is needed, contact Comlinear.

**Controlling Bandwidth and Passband Response**

In most applications, a feedback resistor value of 2kΩ will provide optimum performance; nonetheless, some applications may require a resistor of some other value. The response versus \( R_i \) plot on the previous page shows how decreasing \( R_i \) will increase bandwidth (and frequency response peaking, which may lead to instability). Conversely, large values of feedback resistance tend to roll off the response.

The best settling time performance requires the use of an external feedback resistor (use of the internal resistor results in a 0.1% to 0.2% settling tail). The settling performance may be improved slightly by adding a capacitance of 0.4pF in parallel with the feedback resistor (settling time specifications reflect performance with an external feedback resistor but with no external capacitance).

**Noise Analysis**

Approximate noise figure can be determined for the CLC206 using the equivalent input noise graph on the preceding page and the equations shown below.

**Noise figure is for the network inside this box**

\[
F = 10\log \left[ 1 + \frac{R_S}{R_N} + \frac{R_S}{4kT} \left( i_n + V_n^2 + \frac{R_n}{R_S} + \frac{R_n}{R_S} \right) \right]
\]

where \( R_S = \frac{R_S}{R_N} \); \( A_V = \frac{R_f}{R_S} + 1 \)

\( kT = 4.00 \times 10^{-21} \) Joules at 290°K

\( V_n \) is spot noise voltage (\( V/\sqrt{Hz} \))

\( i_n \) is non inverting spot noise current (\( A/\sqrt{Hz} \))

\( i_i \) is inverting spot noise current (\( A/\sqrt{Hz} \))

**Printed Circuit Layout**

As with any high frequency device, a good PCB layout will enhance the performance of the CLC206. Good ground plane construction and power supply bypassing close to the package are critical to achieving full performance. In the non-inverting configuration, the amplifier is sensitive to stray capacitance to ground at the inverting input. Hence, the inverting node connections should be small with minimal stray capacitance to the ground plane. Shunt capacitance across the feedback resistor should not be used to compensate for this effect.

Evaluation PC boards (part number 730008 for inverting, 730009 for non-inverting) for the CLC206 are available.
APPLICATIONS:
- fast, precision A/D conversion
- wide dynamic range IF amps
- test waveform generation
- VCO drivers
- DDS postamps
- radar/communication receivers
- line drivers

DESCRIPTION:
The CLC207 is a wideband, low distortion operational amplifier designed specifically for applications requiring both high speed and wide dynamic range. Utilizing Comlinear's proprietary current feedback architecture, the CLC207 offers performance far superior to that of conventional voltage feedback op amps.

The most attractive feature of the CLC207 is its extremely low distortion: -80/-85dBc 2nd/3rd harmonics at 20MHz (2Vpp, RLoad = 200Ω). The CLC207 also provides -3dB bandwidth of 170MHz at a gain of +20, settles to 0.1% in 22ns and slew rate at a rate of 2400V/µs, yet is unity-gain stable without external compensation. The combination of these features positions the CLC207 as the right choice for high speed applications requiring exceptional signal purity.

High speed, high resolution A/D and D/A converter systems requiring low distortion operation will find the CLC207 an excellent choice. Wide dynamic range systems such as radar and communication receivers will find that the CLC207's low harmonic distortion and low noise make it an attractive high speed solution.

The addition of the CLC207 to the 205/206 Series of high speed operational amplifiers broadens the selection of features available from which to choose. The CLC205 offers low power operation, the CLC206 offers higher drive operation, and the CLC207 offers operation with extremely low distortion, all of which are pin compatible and overdrive protected.

The CLC207 is constructed using thin-film resistor/bipolar transistor technology and is available in three versions. The CLC207AI is specified over a temperature range of -25°C to +85°C. The CLC207AK, which features burn-in and tested hermeticity, is specified and tested over a temperature range of -55°C to +125°C. The CLC207ASC is specified and tested over a temperature range of -55°C to +125°C and is screened to MIL-STD-883 for high-reliability applications. All three versions come in 12-pin, TO-8 packages. The DESC SMD number is 5962-90977.

- **lead temperature (soldering 10s)**
  - \(+300°C \)

### Notes:
- **note 1:** Parameters preceded by an * are 100% tested. A8 and AK units are tested at -35°C, +25°C and +125°C. AI units are tested at +25°C, though performance at -25°C and +85°C is guaranteed as shown above.
- **note 2:** Settling time specifications require the use of an external feedback resistor (2kΩ).
- **note 3:** In AI units, the noise specifications are guaranteed (but not tested) as shown above. A8 and AK units tested with \( R_L = 200Ω \).
The best settling time performance requires the use of an external feedback resistor. (Use of the internal resistor results in 0.1% to 0.2% settling time.) The settling performance may be improved slightly by adding a capacitance of 0.4pF in parallel with the feedback resistor. (Setting time specifications reflect performance with an external feedback resistor but with no external capacitance.)

**Thermal Model**

\[
P_{\text{circ}} = [(+V_{\text{cc}}) - (-V_{\text{cc}})] / 1.77k\Omega
\]

\[
P_{\text{cw}} = [(+V_{\text{cc}}) - V_{\text{out}} - V_{\text{be}}(R_{\text{f}} + 6)] / (\text{Vcc})
\]

For positive \( V_{\text{cc}} \) and \( V_{\text{be}} \), this is the power in the npn output stage. For negative \( V_{\text{cc}} \) and \( V_{\text{be}} \), this is the power in the pnp output stage.

\[
\theta_{\text{ja}} = 65^\circ\text{C}/\text{W in still air without a heatsink}
\]

35°C/W in still air with a Thermalloy 2268B

15°C/W in 300m/min air with a Thermalloy 2268B (Thermalloy 2240 works equally well.)

\[
I_{\text{out}} = V_{\text{out}} R_{\text{load}} + \text{3mA, whichever is greater}. (\text{Include feedback R in R_{load}})
\]

\[
R_{\text{f}} \text{ is a resistor (33k recommended) between the xxx collector and } \pm V_{\text{cc}}.
\]

\[
T_{1(\text{ppm})} = P_{\text{ppm}} [200 + \theta_{\text{ja}}] + (P_{\text{ppm}} + P_{\text{ppm}}) \theta_{\text{ja}} + T_{\text{a}}
\]

\[
T_{1(\text{ppm})} = P_{\text{ppm}} [17.5 + \theta_{\text{ja}}] + (P_{\text{ppm}} + P_{\text{ppm}}) \theta_{\text{ja}} + T_{\text{a}}
\]

**Printed Circuit Layout**

As with any high frequency device, a good PCB layout will enhance the performance of the CLC207. Good ground plane construction and power supply bypassing close to the package are critical to achieving full performance. In the non-inverting configuration, the amplifier is sensitive to stray capacitance to ground at the inverting input. Hence, the inverting node connections should be small with minimal strain capacitance to the ground plane or other nodes. Shunt capacitance across the feedback resistor should not be used to compensate for this effect.

Evaluation PC boards (part number 730008 for inverting, 730009 for non-inverting) for the CLC207 are available from Comlinear at minimal cost.
APPLICATIONS:
• very high speed D to A, A to D conversion
• high speed fiber optics systems
• baseband and video communications
• radar and IF processors
• very fast risetime pulse amplifiers

DESCRIPTION:
The CLC220 is a wide bandwidth DC-coupled operational amplifier that defines the state-of-the-art in high speed op amps. A -3dB bandwidth of DC to 190MHz is achieved using a proprietary Comlinear design. Ultra-fast settling time (8ns to 0.1%) and slew rate (7000V/µs) make the CLC220 a superior amplifier for pulsed and digital applications.

Since thermal tail has been eliminated, the CLC220 settles fast and remains solidly at the desired level. Flat gain and linear phase (1.2° deviation from linear) from DC to beyond 100MHz help the CLC220 to achieve distortion levels uncommonly low relative to conventional op amps.

Using the CLC220 is as easy as adding power supplies and a gain-setting resistor. The result is reliable, consistent performance because such characteristics as bandwidth and settling time are virtually independent of gain setting. Unlike conventional op amp designs where the optimum gain-bandwidth product occurs at a high gain, minimum settling time at a gain of -1, maximum slew rate at a gain of +1, et cetera, the CLC220 offers predictable response at gain settings from ±1 to ±50. This, coupled with consistent performance from unit to unit with no external compensation, makes the CLC220 a real time and cost-saver in design and production situations alike.

This combination of features makes the CLC220 appropriate for a broad range of applications. The wide bandwidth, DC coupling, and fast settling lend themselves well to high speed D to A and "flash" A to D applications. Both receivers and transmitters in optical fiber systems have similar requirements. High gain and phase linearity and corresponding low distortion make the CLC220 ideal for many digital communication system applications, such as in the demodulator, where the need for both DC coupling and high frequency amplification creates requirements that are difficult to meet.

The CLC220 is constructed using thin-film resistor/bipolar transistor technology. The CLC220A1 is specified over a temperature range of -25°C to +85°C, while the CLC220A8C is specified over a range of -55°C to +125°C and is fully compliant with MIL-STD-883, Level B. Both devices are packaged in 12-pin metal TO-8 cans. The DESC SMD number is 5962-89911.

Equivalent Input Noise

Noise Voltage (mV/Hz)

Noise Current (pA/Hz)

\[ P_{\text{circut}} = \frac{I_{cc}}{2} \left( V_{cc} + V_{out} \right) \] where \( I_{cc} = 26 \text{mA} \) at \( \pm 15 \text{V} \)

\[ P_{\text{XXX}} = \frac{I_{cc}}{2} \left( V_{cc} + V_{out} - \left( I_{cc} \right) \left( R_{\text{COL}} + 4 \right) \right) \] (where cycle)

(For positive \( V_{cc} \) and \( V_{out} \); this is the power in the npn output stage.)

(For negative \( V_{cc} \) and \( V_{out} \); this is the power in the pnp output stage.)

\[ I_{\text{col}} = \frac{V_{out}}{R_{\text{load}}} \text{ or } 4 \text{mA, whichever is greater.} \]

\( R_{\text{COL}} \) is a resistor (330Ω recommended) between the xxx collector and \( V_{cc} \).

\( T_{j}(\text{Case}) = V_{\text{out}}/R_{\text{load}} \) or 4mA, whichever is greater.

\( R_{\text{COL}} \) is a resistor (330Ω recommended) between the xxx collector and \( V_{cc} \).

\( T_{j}(\text{Case}) = V_{\text{out}}/R_{\text{load}} \) or 4mA, whichever is greater.

\( R_{\text{COL}} \) is a resistor (330Ω recommended) between the xxx collector and \( V_{cc} \).

\( T_{j}(\text{Case}) = V_{\text{out}}/R_{\text{load}} \) or 4mA, whichever is greater.

\( R_{\text{COL}} \) is a resistor (330Ω recommended) between the xxx collector and \( V_{cc} \).

\( T_{j}(\text{Case}) = V_{\text{out}}/R_{\text{load}} \) or 4mA, whichever is greater.
Controlling Bandwidth and Passband Response

As with any op amp, the ratio of the two feedback resistors \( R_1 \) and \( R_2 \) determines the gain of the CLC220. Unlike conventional op amps, however, the closed loop pole-zero response of the CLC220 is affected very little by the value of \( R_2 \). \( R_1 \) scales the magnitude of the gain, but does not change the value of the feedback. This is possible due to a proprietary circuit topology. \( R_2 \) does influence the feedback and so the CLC220 has been internally compensated for optimum performance with \( R_1 = 1500\Omega \). External \( R_2 \) values greater than 1500\( \Omega \) can be used with approximate results as listed in Table 1. Use of \( R_2 \) values less than 1500\( \Omega \) will result in extended bandwidth and peaking of the response at high frequencies. For example, \( R_2 = 1000\Omega \) will result in a –3dB bandwidth of about 300MHz, with approximately 3.5dB of peaking above 200MHz. An RC network with a –3dB bandwidth of about 250MHz could be used at the input to flatten the response, although it will reduce the bandwidth of the overall circuit.

Layout Considerations

To assure optimum performance the user should follow good layout practices which minimize the unwanted coupling of signals between nodes. During initial breadboarding of the circuit, use direct point to point wiring, keeping the lead lengths to less than .25". The use of solid, unbroken ground plane is helpful. Avoid wire-wrap type pc boards and methods. Sockets with small, short pin receptacles may be used with minimal performance degradation although their use is not recommended.

During pc board layout, keep all traces short and direct. The resistive body of \( R_2 \) should be as close as possible to pin 5 to minimize capacitance at that point. For the same reason, remove ground plane from the vicinity of pins 5 and 6. In other areas, use as much ground plane as possible on one side of the board. It is especially important to provide a ground return path for current from the load resistor to the power supply bypass capacitors. Ceramic capacitors of .01 to .1\( \mu F \) (with short leads) should be less than .15 inches from pins 1 and 9. Larger tantalum capacitors should be placed within one inch of these pins. \( V_{CC} \) connections to pins 10 and 12 can be made directly from pins 9 and 1, but better supply rejection and settling time are obtained if they are separately bypassed as in Figures 1 and 2. To prevent signal distortion caused by reflections from impedance mismatches, use terminated microstrip or coaxial cable when the signal must traverse more than a few inches.

Since the pc board forms such an important part of the circuit, much time can be saved if prototype boards of any high frequency sections are built and tested early in the design phase. Evaluation boards designed for either inverting or non-inverting gains are available from Comlinear at minimal cost.

Thermal Considerations

At high ambient temperatures or large internal power dissipations, heat sinking is required to maintain acceptable junction temperatures. Use the thermal model on the previous page to determine junction temperatures. Many styles of heat sinks are available for TO-8 packages; the Thermallyon 2240 and 2268 are good examples. Some heat sinks are the radial fin type which cover the pc board and may interfere with external components. An excellent solution to this problem is to use surface mounted resistors and capacitors. They have a very low profile and actually improve high frequency performance. For use of these heat sinks with conventional components, a .1" high spacer can be inserted under the TO-8 package to allow sufficient clearance.

Distortion and Amplification Fidelity

The graphs of intercept point versus frequency on the preceding page make it easy to predict the distortion at any frequency, given the output voltage of the CLC220. First, convert the output voltage (\( V_o \)) to \( V_{nMS} = V_o/2(V_{nMS}) \) and then to \( P = (100\log_{10}(2V_{nMS})) \) to get output power in dBM. At the frequency of interest, its 2nd harmonic will be \( S_2 = 2(\beta - P) \text{dB} \) below the level of \( P \). Its third harmonic will be \( S_3 = 2(\beta - P) \text{dB} \) below \( P \), as will the two-tone third order intermodulation products. These approximations are useful for \( P < -1 \text{dB} \) compression levels.

Approximate noise figure can be determined for the CLC220 using the Equivalent Input Noise graph on the preceding page. The following equation can be used to determine noise figure (\( F \)) in dB.

\[
F = 10\log\left(1 + \frac{V_n^2 + \frac{P}{4KTR_1}\Delta f}{A_n^2}\right)
\]

where \( V_n \) is the rms noise voltage and \( A_n \) is the rms noise current at the inverting node. Beyond the breakpoint of the curves (i.e., where they are flat), broadband noise figure equals spot noise figure, so \( \Delta f \) should equal one (1) and \( V_n \) and \( A_n \) should be read directly off the graph. Below the breakpoint, the noise must be integrated and \( \Delta f \) set to the appropriate bandwidth.

For linear operation of the CLC220 at large output voltage swings (DC component not included) and at high frequencies, observe the (AC output voltage) \( X \) (frequency) product specification of 600V • MHz. Exceeding this rating will cause the signal to be greatly distorted as the amplifier bias control circuit reduces the current available for slewing to prevent damage. At frequencies and voltages within this range the excess slew rate and bandwidth available will ensure the highest possible degree of amplified signal fidelity.

Operation with Reduced Bias Current

Placing a resistor between pins 1 and 2 will cause the CLC220 bias current to be reduced. A value of 20K will cause only a slight reduction, 3K will almost halve the current, while less than 1K will reduce bias to about 5mA and the amplifier will be off. In this condition, the input signal will be greatly attenuated. In the reduced bias, on condition, bandwidth will be roughly proportional to the reduction in bias current. A mechanical or semiconductor switch can be used to turn the amplifier off. Any connection which would cause current to flow out of pin 2 will result in increased bias current and may lead to device destruction from overheating and excessive current.

Application Notes and Assistance

Application notes that address topics such as data conversion, fiber optics, and general high frequency circuit design are available from Comlinear or your Comlinear sales engineer. Comlinear maintains a staff of highly qualified applications engineers to provide technical and design assistance.
APPLICATIONS:

- very high speed D to A, A to D conversion
- high speed fiber optics systems
- baseband and video communications
- radar and IF processors
- very fast risetime pulse amplifiers

DESCRIPTION:

The CLC221 is a wideband operational amplifier designed for the most demanding high-speed applications. State of the art specifications such as the 6500V/µs slew rate and 15ns settling time (to 0.1%) make the CLC221 an excellent choice when system speed is a key concern. In addition to the dynamic parameters, the CLC221 has excellent DC performance; the input offset voltage, for example, is typically only 0.5mV and is guaranteed to be less than 1.0mV at +25°C. The input offset voltage drift is typically only 0.5µV/°C. With this combination of AC and DC parameters, designers are now free of the speed versus accuracy trade-offs common to most high-speed op amps.

The wide bandwidth, DC coupling, and fast settling lend themselves well to high-speed D to A and "flash" A to D applications. Flat gain and phase response and corresponding low distortion make the CLC221 ideal for many digital system applications, such as in the demodulator where the need for both DC coupling and high-frequency amplification creates requirements that are difficult to meet. Engineers desiring to increase the DC performance or large-signal bandwidth of systems using the original CLC220 may replace it with a CLC221 – in most cases with no design changes (they are pin compatible, however the CLC221 does not have a bias control pin).

The dynamic specifications of the CLC221 are due to Comlinear's proprietary op amp topology, a unique design which provides dynamic performance far beyond that of conventional designs. Unlike conventional designs which show vast performance variations over different gains, the CLC221 provides consistent, predictable performance across its entire gain range (see the table below) and since the amplifier is inherently stable, no external compensation is required. This result is shorter design time and the ability to accommodate design changes (in gain, for example) without redesign of compensation circuits or loss of performance.

The CLC221 is constructed using thin-film resistor/bipolar transistor technology. The CLC221AI is specified over a temperature range of −25°C to +85°C, while the CLC221A8C is specified over a range of −55°C to +125°C and is fully compliant with MIL-STD-883, Level B. Both devices are packaged in 12-pin metal TO-8 cans. The DESC SMD number is 5962-90836.

### Supply Voltage (V<sub>CC</sub>)

- ±20V

### Output Current

- ±50mA

### Junction Temperature

- +175°C

### Operating Temperature

- At: −25°C to +85°C
- A8: −55°C to +125°C
- −65°C to +150°C

### Lead Temperature (soldering 10s)

- +300°C

---

**Note 1:** Parameters preceded by an * are the final electrical test parameters and are 100% tested. A8 units are tested at −55°C, +25°C, +125°C. All units are tested only at +25°C although performance at −25°C and +85°C is guaranteed as indicated above.

**Note 2:** This rating protects against damage to the input stage caused by saturation of either the input or output stages. Under transient conditions not exceeding 1μs (duty cycle not exceeding 10%), maximum input voltage may be as large as twice the maximum. V<sub>cm</sub> should never exceed V<sub>CC</sub>(V<sub>CM</sub> is the voltage at the non-inverting input, pin 6).

**Note 3:** This rating protects against exceeding transistor collector-emitter breakdown ratings. Recommended V<sub>CC</sub> is ±15V.
Non-Inverting Gain and Phase

- Gain: $A_v = +4$
- Phase: $A_v = +50$

Inverting Gain and Phase

- Gain: $A_v = -4$
- Phase: $A_v = -50$

Large Signal Gain and Phase

- Gain: $A_v = +20$
- Phase: $A_v = +5$

Small Signal Pulse Response (Inv, Non-Inv)

- Gain: $A_v = +20$
- Phase: $A_v = -20$

2nd and 3rd Harmonic Distortion Intercept

- 2nd harmonic intercept exceeds 105dBm below 500kHz
- 3rd harmonic intercept exceeds 70dBm below 500kHz

Gain vs. Frequency for Various $R_{l,s}$

- $R_L = 50$
- $R_L = 100$
- $R_L = 200$

Settling Time

- 5ns/div

2-Tone 3rd Order Intermod. Intercept

- Intercept Point (+dBm)

CMRR and PSRR

- CMRR
- PSRR

Equivalent Input Noise

- Inverting Current: 250μA/√Hz
- Non-Inverting Current: 280μA/√Hz

Noise Voltage (mV/√Hz)

Gain

- 200°C/W
- 37°C/C

Power (P)

- $P_{\text{Circuit}} = I_C \left( V_C - V_{BE} \right) - I_C \left( V_{BE} - V_{BE} \right)$
- $P_{\text{Pnp}} = I_C \left( V_C - V_{BE} \right)$
- $P_{\text{Pnp}} = I_C \left( V_{BE} - V_{BE} \right)$
- $P_{\text{Circuit}} = I_C \left( V_C - V_{BE} \right)$

Temperature

- $\theta_{JC} = 65°C/W$ in still air without a heatsink
- $\theta_{JC} = 35°C/W$ in still air with a Thermalloy 2268

Ic = $V_{CC}/R_{LOAD}$ or 4mA, whichever is greater.
Figure 1: suggested non-inverting gain circuit

CLC221 Operation
The CLC221 is based on Comlinear's proprietary op amp topology, a unique design that uses current feedback instead of the usual voltage feedback. This design provides dynamic performance far beyond that previously available, yet it is used basically the same as the familiar voltage-feedback op amp (see the gain equations above). A complete discussion of current feedback is given in application note AN300-1.

Controlling Bandwidth and Passband Response
In most applications, use of the internal 1500Ω feedback resistor will provide optimum dynamic performance; nonetheless, some designs may require an external feedback resistor of some value other than 1500Ω. The table below shows how bandwidth depends on the value of Rf. Values of feedback resistance greater than 1500Ω will decrease the bandwidth of the amplifier; values of Rf less than 1500Ω will increase the bandwidth. (At most gain settings, however, low values of Rf may cause instability unless a small amount of compensation capacitance (typically < 0.5pF) is connected in parallel with Rf. At |Ain| < 20, Rf must be greater than 1kΩ).

<table>
<thead>
<tr>
<th>Rf (external)</th>
<th>3dB Bandwidth (Av = 20)</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.5kΩ</td>
<td>150MHz</td>

<td>100MHz</td>
</tr>
<tr>
<td>3kΩ</td>
<td>60MHz</td>
</tr>
<tr>
<td>5kΩ</td>
<td>30MHz</td>
</tr>
</tbody>
</table>

At large closed-loop gains (|Ain| ≥ 50) the bandwidth may be increased by using a low value of Rf as the table below indicates. External compensation is not required under these high-gain conditions.

Figure 2: suggested inverting gain circuit

Since the pc board forms such an important part of the circuit, much time can be saved if prototype boards of any high frequency sections are built and tested early in the design phase. Evaluation boards designed for either inverting or non-inverting gains are available from Comlinear.

Thermal Considerations
At high ambient temperatures or large internal power dissipations, heat sinking is required to maintain acceptable junction temperatures. Use the thermal model on the previous page to determine junction temperatures. Many styles of heat sinks are available for TO-8 packages; the Thermallyx 2240 and 2268 are good examples. Some heat sinks are the radial fin type which cover the pc board and may interfere with external components. An excellent solution to this problem is to use surface mounted resistors and capacitors. They have a very low profile and actually improve high frequency performance. For use of these heat sinks with conventional components, a 1.1" high spacer can be inserted under the TO-8 package to allow sufficient clearance.

Distortion, Noise, and Amplification Fidelity
The graphs of intercept point versus frequency on the preceding page make it easy to predict the distortion at any frequency, given the output voltage of the CLC221. First, convert the output voltage (Vo) to Vrms = (Vp/2√2) and then to P = (10log₁₀(20Vrms²)) to get output power in dBm. At the frequency of interest, its 2nd harmonic will be 2P = (2P₀) dB below the level of P. Its third harmonic will be 3P = (3P₀) dB below P, as will the two-tone third order intermodulation products. These approximations are useful for P < −1dB compression levels.

Approximate noise figure can be determined for the CLC221 using the Equivalent Input Noise graph on the preceding page. The following equation can be used to determine noise figure (F) in dB.

\[ F = 10 \log \left( \frac{\frac{V_n^2}{2} + \frac{i_n^2 R_f^2}{A_v^2}}{4kT R_f \Delta f} \right) \]

where \( V_n \) is the rms noise voltage and \( i_n \) is the rms noise current at the inverting node. Beyond the breakpoint of the curves (i.e., where they are flat), broadband noise figure equals spot noise figure, so Δf should equal one (1) and \( V_n \) and \( i_n \) should be read directly off the graph. Below the breakpoint, the noise must be integrated and Δf set to the appropriate bandwidth.

For linear operation of the CLC221 at large output voltage swings (DC component not included) and at high frequencies, limit the (AC output voltage) × (frequency) product to 1600V-MHz. Exceeding this rating will cause the signal to be greatly distorted as the amplifier bias control circuit reduces the current available for slewing to prevent damage. At frequencies and voltages within this range the excess slew rate and bandwidth available will ensure the highest possible degree of amplified signal fidelity.

Application Notes and Assistance
Application notes that address topics such as data conversion, fiber optics, and general high frequency circuit design are available from Comlinear or your Comlinear sales engineer.

Comlinear maintains a staff of highly qualified applications engineers to provide technical and design assistance.
Fast Settling, Wideband Buff-Amp™ ($A_v = \pm 1$ to $\pm 5$)

APPLICATIONS:
- driving flash A/D converters
- precision line driving
  (a gain of 2 cancels matched-line losses)
- DAC current-to-voltage conversion
- low-power, high-speed applications (50mW @ ± 5V)

DESCRIPTION:
The CLC231 Buff-Amp™ is a wideband operational amplifier designed specifically for high-speed, low-gain applications. The CLC231 is based on Comlinear's proprietary op amp topology—a unique design that both eliminates the gain-bandwidth tradeoff and permits unprecedented high-speed performance. (See table below.)

The CLC231 Buff-Amp™ is the ideal design alternative to low-precision open-loop buffers and oscillation-prone conventional op amps. The CLC231 offers precise gains from ±1.000 to ±5.000 and linearity that is a true .1%—even for demanding 50 ohm loads. Open-loop buffers, on the other hand, offer a nominal gain of .95 ± .03 and a linearity of only 3% for typical loads. A buffer's settling time may look impressive but it is usually specified at unrealistically large load resistances or when the effects of thermal tail are not included; the CLC231 Buff-Amp™ settles to .05% in 15ns—while driving a 100 ohm load.

Offsets and drifts, usually a low priority in conventional high-speed op amp designs, were not ignored in the CLC231; the input offset voltage is typically 1mV and input offset voltage drift is only 10μV/°C. The CLC231 is stable and oscillation-free across the entire gain range and since it’s internally compensated, the user is saved the trouble of designing external compensation networks and having to “tweak” them in production. The absence of a gain-bandwidth tradeoff in the CLC231 allows performance to be predicted easily; the table below shows how the bandwidth is affected very little by changing the gain setting.

The CLC231 is constructed using thin-film resistor/bipolar transistor technology and is available in three versions. The CLC231AI is specified over a temperature range of −25°C to +85°C. The CLC231AK, which features burn-in and tested hermeticity, is specified and tested over a temperature range of −55°C to +125°C. The CLC231ABC is specified and tested over a temperature range of −55°C to +125°C and is fully compliant with MIL-STD-883, Level B. All three versions are packaged in metal 12-pin TO-8 cans. The DESC SMD number is 5962-89594.

FEATURES:
- 165MHz closed-loop − 3dB bandwidth
- 15ns settling to .05%
- 1mV input offset voltage, 10μV/°C drift
- 100mA output current
- excellent AC and DC linearity

- **Output impedance** | 1.3 | <2.5 | <2.5 | <2.5 | pF | CIN |
- **Output voltage range** | at 100MHz | 5.37 | >11 | >11 | >11 | V | VO |

**Input and Common Mode Voltage Limits**

- **Supply voltage** \( V_{cc} \) | ±20V |
- **Output current** | ±100mA |
- **Thermal resistance** (\( T_{th} \)) | see thermal model |
- **Junction temperature** | +175°C |
- **Operating temperature** | At: −25°C to +65°C |
- **Storage temperature** | A8/AK: −55°C to +125°C |
- **Lead temperature** (soldering 10s) | −65°C to +150°C |

**Note 1:** Parameters preceded by an * are the final electrical test parameters and are 100% tested. A8 and AK units are tested at −55°C, +25°C, and +125°C. All units are tested only at +25°C although performance at −25°C and +85°C is guaranteed to be better than or equal to the performance of A8 units over their temperature range.

**Note 2:** The output amplitude used in testing is 0.63Vrms. Performance is guaranteed for conditions listed.

**Note 3:** In the non-inverting configuration, care should be taken when choosing \( R_{i} \), the input impedance setting resistor; bias currents of typically 5μA but as high as 24μA can create an input signal large enough to cause overload. It is therefore recommended that \( R_{i} < \left( \frac{V_{cc}}{I_{B}} \right) / 24μA \).

**Note 4:** These ratings protect against damage to the input stage caused by saturation of either the input or output stages at lower supply voltages, and against exceeding transistor collector-emitter breakdown ratings at high supply voltages. \( V_{out(max)} \) is calculated by assuming no output saturation. Saturation is allowed to occur up to this calculated level of \( V_{out} \). \( V_{cm} \) is defined as the voltage at the non-inverting input, pin 6.
CLC231 Operation
The CLC231 Buff-Amp™ is based on Comlinear’s proprietary op amp topology, a design that uses current feedback instead of the usual voltage feedback. A complete discussion of current feedback is given in application note AN300-1.

The use of the CLC231 is basically the same as that of the conventional op amp (see the gain equations above). Since the device is designed specifically for low gain applications, the best performance is obtained when the circuit is used at gains between ±1 and ±5. Additionally, performance is optimum when a 250Ω feedback resistor is used.

Layout Considerations
To assure optimum performance the user should follow good layout practices which minimize the unwanted coupling of signals between nodes. During initial breadboarding of the circuit, use direct point to point wiring, keeping the lead lengths to less than .25” The use of solid, unbroken ground plane is helpful. Avoid wire-wrap type pc boards and methods. Sockets with small, short pin receptacles may be used with minimal performance degradation although their use is not recommended.

During pc board layout, keep all traces short and direct. The resistive body of Rp should be as close as possible to pin 5 to minimize capacitance at that point. For the same reason, remove ground plane from the vicinity of pins 5 and 6. In other areas, use as much ground plane as possible on one side of the board. It is especially important to provide a ground return path for current from the load resistor to the power supply bypass capacitors. Ceramic capacitors of 01 to 1μF (with short leads) should be less than .15 inches from pins 1 and 9. Larger tantalum capacitors should be placed within one inch of these pins. Vcc connections to pins 10 and 12 can be made directly from pins 9 and 1, but better supply rejection and settling time are obtained if they are separately bypassed as in figures 1 and 2. To prevent signal distortion caused by reflections from impedance mismatches, use terminated microstrip or coaxial cable when the signal must traverse more than a few inches.

Since the pc board forms such an important part of the circuit, much time can be saved if prototype boards of any high frequency sections are built and tested early in the design phase. Evaluation boards designed for either inverting or non-inverting gains are available from Comlinear at minimal cost.

Thermal Considerations
At high ambient temperatures or large internal power dissipations, heat sinking is required to maintain acceptable junction temperatures. Use the thermal model on the previous page to determine junction temperatures. Many styles of heat sinks are available for TO-8 packages; the Thermaloy 2240 and 2268 are good examples. Some heat sinks are the radial fin type which cover the pc board and may interfere with external components. An excellent solution to this problem is to use surface mounted resistors and capacitors. They have a very low profile and actually improve high frequency performance. For use of these heat sinks with conventional components, a .1” high spacer can be inserted under the TO-8 package to allow sufficient clearance.

Low Vcc Operation: Supply Current Adjustment
The CLC231 is designed to operate on supplies as low as ±5V. In order to improve full bandwidth at reduced supply voltages, the supply current (Icc) must be increased. The plot of Bandwidth vs Vcc shows the effect of shorting pins 1 and 2 and pins 8 and 9; this will increase both bandwidth and supply current. Care should be taken to not exceed the maximum junction temperatures; for this reason this technique should not be used with supplies exceeding ±10V. For intermediate values of Vcc, external resistors between pins 1 and 2 and pins 8 and 9 can be used.

Offset Voltage Adjustment
If trimming of the input offset voltage (Vos = Voa - Vob) is desired, a resistor value of 10kΩ to 1MΩ placed between pins 8 and 9 will cause Voa to become more negative by 8mV to 0.2mV respectively. Similarly, a resistor placed between pins 1 and 2 will cause Voa to become more positive.

Distortion and Noise
The graphs of intercept point, I2 and I3, versus frequency on the preceding page make it easy to predict the distortion at any frequency given the output voltage of the CLC231. First, convert the output voltage (Vo) to Vrms = (Vo/2) and then to P = [(10log10(20Vrms²))] to get the power output in dBm. At the frequency of interest, its 2nd harmonic will be S2 = (I2-P)dB below the level of P. Its third harmonic will be S3 = (I3-P)dB below P, as will the two-tone third order intermodulation products. These approximations are useful for P<-1dB compression levels.

Approximate noise figure can be determined for the CLC231 using the equivalent input noise graph on the preceding page. The following equation can be used to determine noise figure (F) in dB.

\[
F = 10 \log \left[ 1 + \frac{\text{i}_n^2 \text{R}_{\text{i}}}{4kT\Delta f} \right]
\]

Where \(v_n\) is the rms noise voltage and \(i_n\) is the rms noise current. Beyond the breakpoint of the curves (i.e., where they are flat), broadband noise figure equals spot noise figure, so \(\Delta f\) should equal one (1) and \(v_n\) and \(i_n\) should be read directly off the graph. Below the breakpoint, the noise must be integrated and \(\Delta f\) set to the appropriate bandwidth.

Application Notes and Assistance
Application notes that address topics such as data conversion, fiber optics, and general high frequency circuit design are available from Comlinear or your Comlinear sales engineer.

Comlinear maintains a staff of highly qualified applications engineers to provide technical and design assistance.
APPLICATIONS:
- flash A/D drivers
- DAC current-to-voltage conversion
- wide dynamic range IF amps
- VCO drivers
- DDS postamps
- radar/communication receivers
- precision line drivers

DESCRIPTION:
The CLC232 is a wideband low distortion operational amplifier designed specifically for high speed, low gain applications requiring wide dynamic range. Utilizing Comlinear’s patented current feedback architecture, the CLC232 offers high speed performance while maintaining DC precision.

The CLC232 offers precise gains from $\pm 1$ to $\pm 5$ with a true 0.1% linearity and provides stable, oscillation-free operation across the entire gain range without external compensation. The CLC232, a pin compatible enhanced version of the CLC231, reduces 2nd and 3rd harmonic distortion to an extremely low $-69$dBc at 20MHz ($2V_{pp}, R_l = 100\Omega$). Additional features provided by the CLC232 include a small signal bandwidth of 270MHz, a large signal bandwidth of 95MHz and a 3000V/µs slew rate. The input offset voltage is typically 1mV with an input offset drift of 10µV/°C.

The CLC232 combines these high performance features with its 0.05% settling time of 15ns and its 100mA drive capability to provide high speed, high resolution A/D and D/A converter systems with an attractive solution for driving and buffering. Wide dynamic range systems such as radar and communication receivers requiring low harmonic distortion and low noise will find the CLC232 to be an excellent choice. As a linedriver, the CLC232 set at a gain of 2 cancels matched line losses.

The CLC232 is constructed using thin-film resistor/bipolar transistor technology and is available in three versions. The CLC232AI is specified over a temperature range of $-25°C$ to $+85°C$. The CLC232AK, which features burn-in and tested hermeticity, is specified and tested over a temperature range of $-55°C$ to $+125°C$. The CLC232ASC is specified and tested over a temperature range of $-55°C$ to $+125°C$ and is fully compliant with MIL-STD-883 for high-reliability applications. All three versions are packaged in metal 12-pin TO-8 packages. The DESC SMD number is 5962-91665.

FEATURES (typical):
- $-69$dBc 2nd and 3rd harmonics at 20MHz
- $-3$dB bandwidth of 270MHz
- 0.05% settling in 15ns
- 3000V/µs slew rate
- 1mV input offset voltage, 10µV/°C drift
- $\pm 10V$, 100mA max output

**Notes:**

1. Parameters preceded by an * are 100% tested. A8 and AK units are tested at -55°C, +25°C and +125°C. All units are tested at +25°C, though performance at -25°C and +85°C is guaranteed as shown above.

2. The output amplitude used in testing is 0.63Vpp. Performance is guaranteed as listed above.

3. In AI units, the noise and distortion specifications are guaranteed (but not tested) as shown above.
Figure 1: suggested non-inverting gain circuit

Figure 2: suggested inverting gain circuit

CLC232 Operation
The CLC232 is based on Comlinear's proprietary op amp topology, a design that uses current feedback instead of the usual voltage feedback. A complete discussion of current feedback is given in application note AN300-1.

The use of the CLC232 is basically the same as that of the conventional op amp (see the gain equations above). Since the device is designed specifically for low gain applications, the best performance is obtained when the circuit is used at gains between ±1 and ±5. Additionally, performance is optimum when a 2500Ω feedback resistor is used.

Layout Considerations
To assure optimum performance the user should follow good layout practices which minimize the unwanted coupling of signals between nodes. During initial broadboarding of the circuit, use direct point to point wiring, keeping the lead lengths to less than .25". The use of solid, unbroken ground plane is helpful. Avoid wire-wrap type pc boards and methods. Sockets with small, short pin receptacles may be used with minimal performance degradation although their use is not recommended.

During pc board layout, keep all traces short and direct. The resistive body of Rf should be as close as possible to pin 5 to minimize capacitance at that point. For the same reason, remove ground plane from the vicinity of pins 5 and 6. In other areas, use as much ground plane as possible on one side of the board. It is especially important to provide a ground return path for current from the load resistor to the power supply bypass capacitors. Ceramic capacitors of .01 to .1µF (with short leads) should be less than .15 inches from pins 1 and 9. Larger tantalum capacitors should be placed within one inch of these pins. Vcc connections to pins 10 and 12 can be made directly from pins 9 and 1, but better supply rejection and settling time are obtained if they are separately bypassed as in Figures 1 and 2. To prevent signal distortion caused by reflections from impedance mismatches, use terminated microstrip or coaxial cable when the signal must traverse more than a few inches.

Since the pc board forms such an important part of the circuit, much time can be saved if prototype boards of any high frequency sections are built and tested early in the design phase. Evaluation boards designed for either inverting or non-inverting gains are available from Comlinear at minimal cost.

Thermal Considerations
At high ambient temperatures or large internal power dissipations, heat sinking is required to maintain acceptable junction temperatures. Use the thermal model on the previous page to determine junction temperatures. Many styles of heat sinks are available for TO-8 packages; the Thermalloy 2240 and 2268 are good examples. Some heat sinks are the radial fin type which cover the pc board and may interfere with external components. An excellent solution to this problem is to use surface mounted resistors and capacitors. They have a very low profile and actually improve high frequency performance. For use of these heat sinks with conventional components, a .1" high spacer can be inserted under the TO-8 package to allow sufficient clearance.

Low Vcc Operation: Supply Current Adjustment
The CLC232 is designed to operate on supplies as low as ±5V. In order to improve full bandwidth at reduced supply voltages, the supply current (Icc) must be increased. The plot of Bandwidth vs Vcc shows the effect of shorting pins 1 and 2 and pins 8 and 9; this will increase both bandwidth and supply current. Care should be taken to not exceed the maximum junction temperatures; for this reason this technique should not be used with supplies exceeding ±10V. For intermediate values of Vcc, external resistors between pins 1 and 2 and pins 8 and 9 can be used.

Offset Voltage Adjustment
If trimming of the input offset voltage (Vos = Vout - Vinput) is desired, a resistor value of 10kΩ to 1MΩ placed between pins 8 and 9 will cause Vos to become more negative by 8mV to 0.2mV respectively. Similarly, a resistor placed between pins 1 and 2 will cause Vos to become more positive.

Thermal Model

Application Notes and Assistance
Application notes that address topics such as data conversion, fiber optics, and general high frequency circuit design are available from Comlinear or your Comlinear sales engineer.

Comlinear maintains a staff of highly qualified applications engineers to provide technical and design assistance.
APPLICATIONS:
- digital communications
- baseband and video communications
- instrument input/output amplifiers
- fast A to D, D to A conversion
- graphic CRT video drive amp
- coaxial cable line driver

DESCRIPTION:
The CLC300 operational amplifier is a unique, proprietary Comlinear design providing a DC-85MHz -3dB bandwidth that is virtually independent of gain setting. Rise and fall times of 4nsec and drive capability of 22Vpp and 100mA add to the CLC300's impressive specifications.

Ease-of-use is a design goal at Comlinear, and the CLC300 is a success in this area as well. Using the CLC300 is as easy as adding power supplies and a gain-setting resistor. And unlike conventional op amp designs in which optimum gain-bandwidth product occurs at a high gain, minimum settling time at a gain of -1, maximum slew rate at a gain of +1, et cetera, the CLC300 offers consistent performance at gain settings from 1 to 40 inverting or non-inverting. As a result, designing with the CLC300 is greatly simplified. And since no external compensation is necessary, “tweaks” on the production line have been eliminated, making the CLC300 an efficient component for use in production situations.

Flat gain and phase response from DC to 45MHz and superior rise and fall times make the CLC300 an ideal amplifier for a broad range of pulse, analog, and digital applications. A 45MHz full power bandwidth (20Vpp into 100Ω) and 3000V/μsec slew rate eliminate the need for power buffers in many applications such as driving “flash” A to D converters or line-driving. For applications requiring lower power consumption, the CLC300 can operate on supplies as low as 5V. Fast overload recovery (20nsec) helps prevent loss of data in communications applications and flat phase response reduces distortion, even when data must be sent over extended lengths of line.

The CLC300A is packaged in a 24-pin ceramic DIP and is specified over a temperature range of -25°C to +85°C. The CLC300B has been discontinued and is no longer in production.

Layout Considerations
To assure optimum performance the user should follow good layout practices which minimize the unwanted coupling of signals between nodes. During initial breadboarding of the circuit, use direct point to point wiring, keeping lead lengths to less than 25". The use of solid, unbroken ground plane is helpful. Avoid wire-wrap type pc boards and methods. Sockets with small, short pin receptacles may be used with minimal performance degradation although their use is not recommended.

Layout Considerations (continued)

During pc board layout keep all traces short and direct. The resistive bodies of $R_F$ and $R_C$ should be as close as possible to pin 8 to minimize capacitance at that point. For the same reason, remove ground plane from the vicinity of pins 8 and 6. In other areas, use as much ground plane as possible on one side of the pc board. It is especially important to provide a ground return path for current from the load resistor to the power supply bypass capacitors. Ceramic capacitors of .01 to .1μF should be close to pins 13 and 16. Larger tantalum capacitors should also be placed within one inch of these pins. To prevent signal distortion caused by reflections from impedance mismatches, use terminated microstrip or coaxial cable when the signal must traverse more than a few inches. Since the pc board forms such an important part of the circuit, much time can be saved if prototype boards of any high frequency sections are built and tested early in the design phase.

Controlling Bandwidth and Passband Response

As with any op amp, the ratio of the two feedback resistors $R_F$ and $R_C$ determines the gain of the CLC300. Unlike conventional op amps, however, the closed loop pole-zero response of the CLC300 is affected very little by the value of $R_C$. $R_F$ scales the magnitude of the gain, but does not change the value of the feedback. This is possible due to a proprietary circuit topology. $R_F$ does influence the feedback and so the CLC300 has been internally compensated for optimum performance with $R_F = 1500\Omega$, but any value of $R_F > 500\Omega$ may be used with a single capacitor placed between pins 8 and 12 for compensation. See Table 1. As $R_F$ decreases, $C_C$ must increase to maintain flat gain. Large values of $R_F$ and $C_C$ can be used together or separately to reduce the bandwidth. This may be desirable for reducing the noise bandwidth in applications not requiring the full frequency response available.

Low Gain Operation

The small amount of stray capacitance present at the inverting input can cause peaking which increases with decreasing gain. The gain setting resistor $R_C$ is effectively in parallel with this capacitance and so a frequency domain pole results. With small $R_C$ (Gain > 8), this pole is at a high frequency and it affects the closed loop gain of the CLC300 only slightly. At lower values of gain, this pole becomes significant. For example, at a gain of ±2, the gain may peak as much as 3dB at 75MHz, and have a bandwidth exceeding 150MHz. The same behavior does not exist for low inverting gains, however, since the inverting input is a virtual ground which maintains a constant voltage across the stray capacitance. Even at inverting gains << 1, the frequency response remains unchanged.

To avoid the peaking at low non-inverting gains, place a resistor $R_S$ in series with the input signal path just ahead of pin 6, the non-inverting input. This forms a low pass filter with the capacitance at pin 6 which can be made to cancel the peaking due to the capacitance at pin 8, the inverting input. At a gain of ±2, for example, choosing $R_S$ such that the source impedance in parallel with $R_S$ (see Figure 1), plus $R_F$ equals 1750Ω will flatten the frequency response. For larger gains, $R_S$ will decrease.

Settling Time, Offset, and Drift

After an output transition has occurred, the output settles very rapidly to final value and no change occurs for several microseconds. Thereafter, thermal gradients inside the CLC300 will cause the output to begin to drift. When this cannot be tolerated, or when the initial offset voltage and drift is unacceptable, the use of a composite amplifier is advised. This technique reduces the offset and drift to that of a monolithic, low frequency op amp, such as an LF356A. The composite amplifier technique is fully described in the CLC103 Data Sheet.

A simple offset adjustment can be implemented by connecting the wiper of a potentiometer, whose end terminals connect to ±15V, through a 20K resistor to pin 8 of the CLC300. Variations of this technique are described in Application Note 200-1, Designer's Guide for 200 Series Op Amps.

Overload Protection

To avoid damage to the CLC300, care must be taken to insure that the input voltage does not exceed (1/2 $V_{oc}$ - 2.5)/$A_V$. High speed, low capacitance diodes should be used to limit the maximum input voltage to safe levels if a potential for overload exists.

If in the non-inverting configuration the resistor $R_C$, which sets the input impedance, is large, the bias current at pin 6, which is typically a few μA but which may be as large as 18μA, can create a large enough input voltage to exceed the overload condition. It is therefore recommended that $R_C < (1/2 A_V)$/(18μA).

Distortion and Noise

The graphs of intercept point versus frequency on the preceding page make it easy to predict the distortion at any frequency, given the output voltage of the CLC300. First, convert the output voltage ($V_o$) to $V_{rms} = V_o/\sqrt{2}$ and then to $P = 10\log_{10}(20V_{rms})$ to get output power in dBm. At the frequency of interest, its 2nd harmonic will be $S_2 = (I_2 - P)$ below the level of $P$. Its third harmonic will be $S_3 = (I_3 - P)$ dB below $P$, as will the two tone third order intermodulation products. These approximations are useful for $P < -1$dB compression levels.

Approximate noise figure can be determined for the CLC300 using the Equivalent Input Noise graph on the preceding page. The following equation can be used to determine noise figure ($F$) in dB:

\[
F = 10\log_{10}\left[1 + \frac{\nu_n^2 + i_n^2 R_F^2}{A_V^2 4kT R_C \Delta f}\right]
\]

where $\nu_n$ is the rms noise voltage and $i_n$ is the rms noise current. Beyond the breakpoint of the curves (i.e., where they are flat), broadband noise figure equals spot noise figure, so $\Delta f$ should equal one (1) and $\nu_n$ and $i_n$ should be read directly off of the graph. Below the breakpoint, the noise must be integrated and $\Delta f$ set to the appropriate bandwidth.

Application Notes

For information on the use of the CLC300 in a wide variety of applications, refer to application note AN200-1.
APPLICATIONS:
- fast, precision A/D conversion
- video distribution
- line drivers
- D/A current-to-voltage conversion
- photodiode, CCD preamps
- IF processors
- high-speed communications

FEATURES:
- $-3\db$ bandwidth of 200MHz
- 0.05% settling in 12ns
- low power, 150mW
- low distortion, $-60\dbc$ at 20MHz
- stable without compensation
- overload and short circuit protected
- $\pm1$ to $\pm8$ closed-loop gain range

DESCRIPTION:
The CLC400 is a high-speed, fast-settling operational amplifier designed for low-gain applications. Constructed using a unique, proprietary design and an advanced complementary bipolar process, the CLC400 offers performance far beyond that normally offered by ordinary monolithic op amps. In addition, unlike many other high-speed op amps the CLC400 offers both high performance and stability without the need for compensation circuitry—even at a gain of $+1$.
The fast 12ns settling to 0.05% and its ability to drive capacitive loads makes the CLC400 an ideal flash A/D driver. The wide bandwidth of 200MHz and the very linear phase ensure unsurpassed signal fidelity.

Systems employing digital to analog converters also benefit from the use of the CLC400 especially if linearity and drive levels are important to system performance.

The CLC400 provides a simple, high-performance solution for video distribution and line driving applications. The 50mA output current and guaranteed specifications for 100 ohm loads provide ample drive capability and assured performance.

The CLC400 is available in several versions to meet a variety of requirements. A three-letter suffix determines the version:

- CLC400AJP - $40°C$ to $+85°C$ 8-pin plastic DIP
- CLC400AJE - $40°C$ to $+85°C$ 8-pin plastic SOIC
- CLC400AIB - $40°C$ to $+85°C$ 8-pin hermetic CERDIP
- CLC400ABB - $55°C$ to $+125°C$ dice
- CLC400AIB - $55°C$ to $+125°C$ dice qualified to Method 500, MIL-STD-883, Level B
- CLC400AMC - $55°C$ to $+125°C$ dice qualified to Method 5008, MIL-STD-883, Level B

The CLC400 is based on Comlinear’s proprietary op amp topology that uses current feedback instead of the usual voltage feedback. This unique design has many advantages over conventional designs (such as settling time that is relatively independent of gain), yet it is used in basically the same way (see the gain equations in Figures 1 and 2, page 4). However, an understanding of the topology will aid in achieving the best performance. The following discussion will proceed for the non-inverting gain configuration with the inverting mode analysis being very similar.

#### FREQUENCY DOMAIN RESPONSE

- **t-3dB bandwidth**: $V_{\text{out}} < 0.5V_{pp}$
  - **gain flatness**: $A_v = +5$
  - **peak**: $< 40\text{MHz}$
  - **rolloff**: $> 75\text{MHz}$
  - **linear phase deviation**: to $75\text{MHz}$

#### TIME DOMAIN RESPONSE

- **rise and fall time**: 0.5V step, 5V step
- **settling time to ±0.1%**: 2V step, 2V step
- **overshoot**: 0.5V step
- **slew rate $A_v = +2$**: 700
- **$A_v = -2$**: 1600

#### DISTORTION AND NOISE RESPONSE

- **2nd harmonic distortion**: $2V_{pp}, 20\text{MHz}$
  - **3rd harmonic distortion**: $2V_{pp}, 20\text{MHz}$
  - **noise floor**: $> 1\text{MHz}$
  - **integrated noise**: $1\text{MHz}$ to $200\text{MHz}$

#### STATIC, DC PERFORMANCE

- **input offset voltage**: 2
- **average temperature coefficient**: ±8.2
- **input bias current**
  - **non-inverting**: 20
  - **inverting**: 10
- **average temperature coefficient**: ±5.0
- **input bias current**
  - **non-inverting**: ±40
  - **inverting**: ±36
- **average temperature coefficient**: ±9.0
- **input bias current**
  - **non-inverting**: ±40
  - **inverting**: ±36
- **average temperature coefficient**: ±9.0
- **supply current no load**: ±50
- **common mode rejection ratio**: ±50
- ***supply rejection ratio**: ±50

#### MISCELLANEOUS PERFORMANCE

- **non-inverting input resistance**: 200
- **capacitance**: ±50
- **output impedance at DC**: 0.1
- **output voltage range**: ±3.5
- **common mode input range**: ±2.1
- **output current**: ±70
- **output current**
  - $-40\text{°C}$ to $+85\text{°C}$
  - $-55\text{°C}$ to $+125\text{°C}$

Understanding the Loop Gain

Referring to the equivalent circuit of Figure 3, any current flowing in the inverting input is amplified to a voltage at the output through the transimpedance gain shown on the plots on page 3. This $Z(s)$ is analogous to the open-loop gain of a voltage feedback amplifier.

Figure 1: recommended non-inverting gain circuit

Developing the non-inverting frequency response for the topology of Figure 3 yields:

$$V_o = \frac{1 + R_1/R_2}{1 - 1/LG} \quad \text{Eq. (1)}$$

where $LG = \frac{Z(s)}{R_1} \times \frac{1}{1 + Z/s(R_1 | R_2)} \quad \text{Eq. (2)}$

Equation 1 has a form identical to that for a voltage feedback amplifier with the differences occurring in the LG expression, Equation 2. For an idealized treatment, set $Z = 0$ which results in a very simple $LG = Z(s)/R_1$ (Derivation of the transfer function for the case where $Z = 0$ is given in Application Note AN300-1). Using the $Z(s)$ (open-loop transimpedance gain) plot shown on the previous page and dividing by the recommended $R_1 = 250\Omega$, yields a large loop gain at DC. As a result, Equation 1 shows that the closed-loop gain at DC is very close to $1 + R_1/R_2$.

At higher frequencies, the roll-off of $Z(s)$ determines the closed-loop frequency response which, ideally, is dependent only on $R_2$. The specifications reported on the previous pages are therefore valid only for the specified $R_1 = 250\Omega$. Increasing $R_1$ from $250\Omega$ will decrease the loop gain and bandwidth, while decreasing it will increase the loop gain possibly leading to inadequate phase margin and closed-loop peaking. Conversely, fixing $R_1$ will hold the frequency response constant while the closed-loop gain can be adjusted using $R_2$.

The CLC400 deviates from this idealized analysis to the extent that the inverting input impedance is finite. With the low quiescent power of the CLC400, $Z = 50\Omega$ leading to a drop in loop gain and bandwidth at high gain settings, as given by Equation 2. The second term in Equation 2 accounts for the division in feedback current that occurs between $Z$ and $R_1/R_2$ at the inverting node of the CLC400. This decrease in bandwidth can be circumvented as described in “Increasing Bandwidth at High Gains.”

DC Accuracy and Noise

Since the two inputs for the CLC400 are quite dissimilar, the noise and offset error performance differs somewhat from that of a standard differential input amplifier. Specifically, the inverting input current noise is much larger than the non-inverting current noise. Also the two input bias currents are physically unrelated rendering bias current cancellation through matching of the inverting and non-inverting pin resistors ineffective.

In Equation 3, the output offset is the algebraic sum of the equivalent input voltage and current sources that influence DC operation. Output noise is determined similarly except that a root-sum-of-squares replaces the algebraic sum. $R_s$ is the non-inverting pin resistance.

$$\text{Output Offset} V_o = \pm IB \times R_s$$

An important observation is that for fixed $R_s$, offsets as referred to the input improve as the gain is increased (divide all terms by $1 + R_1/R_2$). A similar result is obtained for noise where noise figure improves as gain increases.

Selecting Between the CLC400 or CLC401

The CLC400 is intended for gains of $\pm 1$ to $\pm 8$ while the CLC401 is designed for gains of $\pm 7$ to $\pm 50$. Optimum performance is achieved with a feedback resistor of $250\Omega$ with the CLC400 and $1.5k\Omega$ with the CLC401—this distinction may be important in transimpedance applications such as D/A buffering. Although the CLC400 can be used at higher gains, the CLC401 will provide a wider bandwidth because loop gain losses due to finite $Z$ are lower with the larger CLC401 feedback resistor as explained above. On the other hand, the lower recommended feedback resistance of the CLC401 minimizes the output errors due to inverting input noise and bias currents.

Increasing Bandwidth At High Gains

Bandwidth may be increased at high closed-loop gains by adjusting $R_1$ and $R_2$ to make up for the losses in loop gain that occur at these high gain settings due to current division at the inverting input. An approximate relationship may be obtained by holding the LG expression constant as the gain is changed from the design point used in the specifications (that is, $R_1 = 250\Omega$ and $R_2 = 250\Omega$). For the CLC400 this gives,

$$R_1 = 350 - 50A \quad \text{and} \quad R_2 = \frac{350 - 50A}{1 - A} \quad \text{Eq. (4)}$$

where $A$ is the non-inverting gain. Note that with $A = \pm 2$ we get the specified $R_1 = 250\Omega$, while higher gains, a lower value gives stable performance with improved bandwidth.

Capacitive Feedback

Capacitive feedback should not be used with the CLC400 because of the potential for loop instability. See Application Note OA-7 for active filter realizations with the CLC400.

Offset Adjustment Pin

Pin 1 can be connected to a potentiometer as shown in Figure 1 and used to adjust the input offset of the CLC400. Full range adjustment of $\pm 5V$ on pin 1 will yield a $\pm 10mV$ input offset adjustment range. Pin 1 should always be bypassed to ground with a ceramic capacitor located close to the package for best settling performance.

Printed Circuit Layout

As with any high frequency device, a good PCB layout will enhance performance. Ground plane construction and good power supply bypassing close to the package are critical to achieving full performance. In the non-inverting configuration, the amplifier is sensitive to stray capacitance to ground at the inverting input. Hence, the inverting node connections should be small with minimal coupling to the ground plane. Shunt capacitance across the feedback resistor should not be used to compensate for this effect.

Parasitic or load capacitance directly on the output will introduce additional phase shift in the loop degrading the loop phase margin and leading to frequency response peaking. A small series resistor before the capacitance effectively decouples this effect. The graphs on the preceding page illustrate the required resistor value and resulting performance vs. capacitance.

Precision buffered resistors (PRP8351 series from Precision Resistive Products) with low parasitic reactances were used to develop the data sheet specifications. Precision carbon composition resistors will also yield excellent results. Standard spirally-trimmed RN55D metal film resistors will work with a slight decrease in bandwidth due to their reactive nature at high frequencies.

Evaluation PC boards (part no. 730013 for through-hole and 730027 for SOIC) for the CLC400 are available.
APPLIcATIONS:
• fast, precision A/D conversion
• photodiode, CCD preamps
• IF processors
• high-speed modems, radios
• line drivers
• DC-coupled log amplifiers
• high-speed communications

DESCRIPTION:
The CLC401 is a wideband, fast-settling op amp designed for applications requiring gains greater than ±7. Constructed using an advanced complementary bipolar process and a proprietary design, the CLC401 features dynamic performance far beyond that of typical high-speed monolithic op amps. For example, at a gain of +20, the −3dB bandwidth is 150MHz and the rise/fall time is only 2.5ns.

The wide bandwidth and linear phase (0.2° deviation from linear at 50MHz) and a very flat gain response makes the CLC401 ideal for many digital communication system applications. For example, demodulators need both DC coupling and high-frequency amplification – requirements that are ordinarily difficult to meet.

The very fast 10ns settling to 0.1% and the ability to drive capacitive loads lend themselves well to flash A/D applications. Systems employing D/A converters also benefit from the settling time and also by the fact that current-to-voltage transimpedance amplification is easily accomplished.

The CLC401 provides a quick, effective design solution. Its stable operation over the entire ±7 to ±50 gain range precludes the need for external compensation. And, unlike many other high-speed op amps, the CLC401’s power dissipation of 150mW is compatible with designs which must limit total power dissipation or power supply requirements.

The CLC401 is available in several versions to meet a variety of requirements. A three-letter suffix determines the version:

CLC401 AJP -40°C to +85°C 8-pin plastic DIP
CLC401 AJE -40°C to +85°C 8-pin plastic SOIC
CLC401 AIB -40°C to +85°C 8-pin hermetic CERDIP
CLC401 A8B -55°C to +125°C 8-pin hermetic CERDIP, MIL-STD-883, Level B
CLC401 ALC -55°C to +125°C dice
CLC401 AMC -55°C to +125°C dice-qualified to Method 5008, Operation

The CLC401 is based on Comlinear’s proprietary op amp topology that uses current feedback instead of the usual voltage feedback. This unique design has many advantages over conventional designs (such as settling time that is relatively independent of gain), yet it is used in basically the same way (see the gain equations in Figures 1 and 2, page 4).

Recommended $R_s$ vs. Load Capacitance

Low Gain & Transimpedance Applications

The CLC401 may be used at gains down to unity ($A_v = 1$) by choosing $R_s$ according to Equation (4) on the following page. The curves to the right show performance at inverting unity gain with $R_s = 25000$, a configuration appropriate for D/A converter buffering and other transimpedance applications.
ever, an understanding of the topology will aid in achieving the best performance. The discussion below will proceed for the non-inverting gain configuration with the inverting mode analysis being very similar.

**Understanding the Loop Gain**

Referring to the equivalent circuit of Figure 3, any current flowing in the inverting input is amplified to a voltage at the output through the transimpedance gain shown on the plot on page 3. This \( Z(s) \) is analogous to the open-loop gain of a voltage feedback amplifier.

Developing the non-inverting frequency response for the topology of Figure 3 yields:

\[
\frac{V_o}{V_i} = \frac{1 + R_i/R_g}{1 - 1/LG} \quad \text{eq. (1)}
\]

where LG is the loop gain defined by,

\[
LG = \frac{Z(s)}{R_f} \times \frac{1}{1 + \frac{Z_i}{R_i + R_g}} \quad \text{eq. (2)}
\]

Equation 1 has a form identical to that for a voltage feedback amplifier with the differences occurring in the LG expression. For an idealized treatment, set \( Z_i = 0 \) which results in a very simple \( LG = Z(s)/R_f \).

(Derivation of the transfer function for the case where \( Z_i = 0 \) is given in Application Note AN300-1) Using the \( Z(s) \) (open-loop transimpedance gain) plot shown on the previous page and dividing by the recommended \( R_i = 1.5k\Omega \), yields a large loop gain at DC. As a result, equation 1 shows that the closed-loop gain at DC is very close to \( (1 + R_i/R_g) \).

At higher frequencies, the roll-off of \( Z(s) \) determines the closed-loop frequency response which, ideally, is dependent only on \( R_f \). The specifications reported on the previous pages are therefore valid only for the specified \( R_f = 1.5k\Omega \). Increasing \( R_f \) from 1.5k\Ω will decrease the loop gain and bandwidth, while decreasing it will increase the loop gain possibly leading to inadequate phase margin and closed-loop peaking. Conversely, fixing \( R_f \) will hold the frequency response constant while the closed-loop gain can be adjusted using \( R_g \).

The CLC401 departs from this idealized analysis to the extent that the inverting input impedance is finite. With the low quiescent power of the CLC401, \( Z_i = 500 \) leading to a loop gain and bandwidth at high gain settings, as given by equation 2. The second term in equation 2 accounts for the division in feedback current that occurs between \( Z_i \) and \( R_i + R_g \) at the inverting node of the CLC400. This decrease in bandwidth can be circumvented as described in “Increasing Bandwidth at High Gains.”

**DC Accuracy and Noise**

Since the two inputs for the CLC401 are quite dissimilar, the noise and offset error performance differs somewhat from that of a standard differential input amplifier. Specifically, the inverting input current noise is much larger than the non-inverting current noise. Also the two input bias currents are physically unrelated rendering bias current cancellation through matching of the inverting and non-inverting pin resistors ineffective.

In equation 3, the output offset is the algebraic sum of the equivalent input voltage and current sources that influence DC operation. Output noise is determined similarly except that a root-sum-of-squares replaces the algebraic sum. \( R_g \) is the non-inverting pin resistance.

For optimum performance, \( R_f \) and \( R_g \) should be low-inductance, low-capacitance resistors. (Pin designations are for DIP versions.)
APPLICATIONS:
- high-accuracy A/D systems (12-14 bits)
- high-accuracy D/A converters
- high-speed communications
- IF signal processing
- video distribution

DESCRIPTION:
The CLC402 is an operational amplifier designed for low-gain applications (±1 to ±8), requiring fast, accurate settling and superior DC accuracy. Settling to 0.0025% in 25ns (32ns guaranteed over temperature), the CLC402 is ideal as the input amplifier in high accuracy (up to 14-bits) A/D systems. Unlike most other high-speed op amps, the CLC402 is free of thermally induced tails in the settling response.

The CLC402 is an upgrade to and pin compatible with the industry standard CLC400. Constructed using a unique, proprietary design and an advanced complementary bipolar process, it offers performance far beyond ordinary monolithic op amps. In addition, unlike many other high-speed op amps, the CLC402 offers both high performance and stability without the need for compensation circuitry – even at a gain of +1.

Supporting the CLC402’s excellent pulse performance are improved DC characteristics. The CLC402’s input offset voltage is typically 0.5mV and is guaranteed to be less than 1.6mV at +25°C. The input offset voltage drift is typically only 3μV/°C.

The CLC402 is available in several versions to meet a variety of requirements. A three-letter suffix determines the version:
- CLC402AJP – 40°C to +85°C 8-pin plastic DIP
- CLC402AJE – 40°C to +85°C 8-pin plastic SOIC
- CLC402AID – 40°C to +85°C 8-pin hermetic side-brazed ceramic DIP
- CLC402A8D – 55°C to +125°C 8-pin hermetic side-brazed ceramic DIP, MIL-STD-883, Level B
- CLC402ALC – 55°C to +125°C dice

Contact factory for other packages. DESC SMD number, 5962-92033.

FEATURES (typical):
- 0.0025% settling in 25ns (32ns max.)
- 0.5mV input offset voltage, 3μV/°C drift
- ±1 to ±8 closed-loop gain range
- low power, 150mW
- 0.01%/0.05° differential gain/phase

PINOUT
- 8-pin plastic DIP
- 8-pin side-brazed ceramic DIP
- 8-pin plastic SOIC

Feedback Resistor
The CLC402 achieves its excellent pulse response by using the current feedback topology pioneered by Comlinear Corporation. The loop gain for a current feedback op amp, and hence the frequency response, is predominantly set by the feedback resistor value. The CLC402 is optimized for use with a 250Ω feedback resistor. Using lower values can lead to excessive ringing in the pulse response while a higher value will limit the bandwidth. Application Note OA-13 discusses this in detail along with occasions where a different Rf might be advantageous.

Optimizing Settling Time
The CLC402 is capable of extremely fast pulse settling times to very fine scale accuracies (.0025% in 25ns typical). It is also virtually free of any measurable thermal tail effects as shown in the long-term settling time plot on the previous page. Careful attention to parasitic effects is critical to achieving this level of performance.

Generally, open any ground and/or power planes around the device while providing an adjacent ground plane for the 0.1µF ceramic decoupling caps. These caps should be very near the power pins. Connecting the ground return point for the electrolytic capacitors near the load ground point is also very useful. Similarly, for non-inverting applications, connecting Rq to ground near the input terminating resistor ground connection will improve performance. These suggestions become particularly pertinent for fastest settling to lower than 0.1% accuracies.

Using Supply Resistors, Rs
Figures 1 and 2 show a series resistor in the supply leads between the electrolytic and ceramic capacitors. This optional resistor is intended to de-Q any self-resonance between those capacitors and the power supply trace inductance. Any large output voltage step into a significant load, either resistive or capacitive, will necessarily pull a current surge through the supply de-coupling capacitors. This can cause a very low level, high frequency ringing on the power supplies that may not be effectively rejected by the PSRR of the CLC402. This can, in turn, show up at the output as a ringing that will preclude high speed settling to very fine scale accuracies.

Adding Rs will increase the amplitude of this signal at the supplies but will lower the frequency content to where the CLC402’s PSRR can effectively reject it. An Rs of 5 to 10Ω will yield excellent settling performance with minimal impact on other performance parameters.

Driving Capacitive Loads
Either parasitic or load capacitance directly on the output pin can quickly lead to unacceptable levels of ringing in the pulse response. Adding a series resistor, as shown in the plot of Rs vs. C1 on the previous page, will resolve this problem. Parasitic capacitances less than 2pF can be driven without the series resistor. See Application Note OA-15 for additional discussion.

Distortion Performance
The distortion plots show the harmonic distortions and 3rd order intermodulation intercepts under a variety of load, power, and frequency conditions. Generally, going to higher frequencies will degrade the distortion performance as the amplifier loop gain decreases. Further distortion improvements at low frequencies are observed when driving higher impedance loads. The 3rd order intermodulation intercept plot may be used to predict the 3rd order spurious levels given the power levels at the load for two closely spaced signal frequencies. Figure 3 shows the signal and spurious level definitions along with equations for predicting the spurious powers from the intercept value and the two signal powers.

DC Accuracy and Noise
The CLC402 offers an improved offset voltage over the comparable CLC400 low gain amplifier. The offset adjustment available on the CLC400 was therefore not included in this part. Figure 4 shows the output offset computational equation for the non-inverting configuration with an example using the typical bias current and offset specifications for Aν = +2.

Output Offset
\[ V_o = \left( \pm 10\mu A / (500\Omega) \right) \left( 1 + \frac{R_1}{R_3}\right) \pm h_v R_1 \]
Example computation for Aν = +2, Rs = 250Ω

The equivalent input noise plot shows that the CLC402 offers a low 1.7nV/√Hz input noise voltage. A low non-inverting source impedance should be used for lowest noise performance due to the relatively high current noise at that input. See Application Note OA-7 for a full discussion of noise calculations for current feedback amplifiers.

Printed Circuit Layout
Evaluation PC boards (part number 730013 for through-hole and 730027 for SOIC) for the CLC402 are available. This board can be easily modified to include the Rs resistors discussed above. Further layout suggestions may be found in Application Note OA-15.
APPLICATIONS:
• fast A/D conversion
• line driving
• video distribution
• high-speed communications
• radar, IF processors

DESCRIPTION:
The CLC404 is a high-speed, monolithic op amp that combines low power consumption (110mW typical, 120mW maximum) with superior large signal performance. Operating off of ±5V supplies, the CLC404 demonstrates a large-signal bandwidth (5Vpp output) of 165MHz. The bandwidth performance, along with other speed characteristics such as rise and fall time (2.1 ns for a 5V step), is nearly identical to the small signal performance since slew rate is not a limiting factor in the CLC404 design.

With its 175MHz bandwidth and 10ns settling (to 0.2%), the CLC404 is ideal for driving ultra-fast flash A/D converters. The 0.5° deviation from linear phase, coupled with -53dBc 2nd harmonic distortion and -60dBc 3rd harmonic distortion (both at 20MHz), is well suited for many digital and analog communication applications. These same characteristics, along with 70mA output current, differential gain of 0.07%, and differential phase at 0.03°, make the CLC404 an appropriate high-performance solution for video distribution and line driving applications.

Constructed using an advanced, complementary bipolar process and Comlinear's proven current feedback topologies, the CLC404 provides performance far beyond that of other monolithic op amps. The CLC404 is available in several versions to meet a variety of requirements. A three-letter suffix determines the version:

- CLC404AJP - 40°C to +85°C 8-pin plastic DIP
- CLC404AJE - 40°C to +85°C 8-pin plastic SOIC
- CLC404AID - 40°C to +85°C 8-pin hermetic side-brazed ceramic DIP
- CLC404ABD - 55°C to +125°C 8-pin hermetic side-brazed ceramic DIP, MIL-STD-883, Level B
- CLC404ALC - 55°C to +125°C dice
- CLC404AMC - 55°C to +125°C dice qualified to Method 5008, MIL-STD-883, Level B

Contact factory for other packages. DESC SMD number, 5962-90994.

FEATURES (typical):
• 165MHz large signal bandwidth (5Vpp)
• 2600V/µs slew rate
• low power: 110mW
• low distortion: -53dBc at 20MHz
• 10ns settling to 0.2%
• 0.07% differential gain, 0.03° differential phase

Slew Rate

Slew rate limiting is a nonlinear response which occurs in amplifiers when the output voltage swing approaches hard, abrupt limits in the speed at which it can change. In most applications, this results in an easily identifiable “slew rate” as well as a dramatic increase in distortion for large signal levels. The CLC404 has been designed to provide enough slew rate to avoid slew rate limiting in almost all circuit configurations. The large signal bandwidth of 165MHz, therefore, is nearly the same as the 175MHz small signal bandwidth. The result is a low-distortion, linear system for both small signals and large signals.

Slew rate and large signal performance in the CLC404 can best be understood by first comparing the small and large signal performance plots at a gain of +6. In the CLC404, there is almost no difference between large and small signal performance at this gain. Large signal performance in the CLC404 at a gain of +6 is not slew rate limited. (In an amplifier which is slew limiting, the large signal response rolloff has an abrupt break indicating the onset of slew rate limitation.)

The CLC404 reaches slew rate limits only for low non-inverting gains. In other words, slew rate limiting is constrained by common mode voltage swings at the input. (This is different from traditional slew rate constraints.) The large-signal frequency response plot at a gain of +2 shows a break in the response, which shows that slew rate limit has been reached. Note also that the frequency response plots at gain of +21 show that the large signal and small signal responses are nearly identical.

Differential Gain and Phase

Differential gain and phase are measurements useful primarily in composite video channels. Differential gain and phase are measured by monitoring the gain and phase of a high frequency carrier (3.58MHz for NTSC composite video) as the output of the amplifier is swept over a range of DC voltages. Any changes in gain and phase at the carrier frequency are the desired measurement, differential gain and phase.

Specifications for the CLC404 include differential gain and phase. The test signals used are based on a 1Vpp video level. Test conditions used are the following:

DC sweep range: 0 to 100 IRE units (black to white)
Carrier: 3.58MHz at 40 IRE units peak to peak

The amplifier is specified for a gain of +2, and 150Ω load (for a backmatched 75Ω system). IRE amplitudes are referred to 75Ω, at the load of a video system. This is a different condition from the rest of the specifications ($A_v = +6, R_l = 100Ω$).

Source Impedance

For best results, source impedance in the non-inverting circuit configuration (see Figure 1) should be kept below 3kΩ. Above 3kΩ it is possible for oscillation to occur, depending on other circuit parasitics. Depending on the signal source, a resistor with a value of less than 3kΩ may be used to terminate the non-inverting input to ground.

Feedback Resistor

In current-feedback op amps, the value of the feedback resistor plays a major role in determining amplifier dynamics. It is important to select the correct value resistor. The CLC404 provides optimum performance with a 5kΩ feedback resistor. Furthermore, the specifications shown on the previous pages are valid only when a 5kΩ feedback resistor is used. Selection of an incorrect value can lead to severe rolloff in frequency-response (if the resistor value is too large) or peaking or oscillation (if the value is too low). See Comlinear application notes AN and AN 300-1 for a complete discussion of current feedback.

Printed Circuit Layout

As with any high frequency device, a good PCB layout will enhance performance. Ground plane construction and good power supply bypassing close to the package are critical to achieving full performance. In the non-inverting configuration, the amplifier is sensitive to stray capacitance to ground at the inverting input. Hence, the inverting node connections should be small with minimal coupling to the ground plane. Shunt capacitance across the feedback resistor should not be used to compensate for this effect.

Parasitic or load capacitance directly on the output will introduce additional phase shift in the loop degrading the loop phase margin and leading to frequency response peaking. A small series resistor before the capacitance effectively decouples this effect. The graphs on the preceding page illustrate the required resistor value and resulting performance vs. capacitance.

Precision buffered resistors (PRP353 series from Precision Resistive Products) with low parasitic reactances were used to develop the data sheet specifications. Precision carbon composition resistors will also yield excellent results. Standard spirally-trimmed RN55D metal film resistors will work with a slight decrease in bandwidth due to their reactive nature at high frequencies.

Evaluation PC boards (part number 730013 for through-hole and 730027 for SOIC) for the CLC404 are available.
Applications:
- video distribution amp
- HDTV amplifier
- flash A/D driver
- D/A transimpedance buffer
- pulse amplifier
- photo-diode amp
- LAN amplifier

Description:
The CLC406 is a wideband monolithic operational amplifier designed for low-gain applications where power and cost are of primary concern. Operating from ±5V supplies, the CLC406 consumes only 50mW of power yet maintains a 160MHz small signal bandwidth and a 1500V/µs slew rate. Benefitting from Comlinear’s current feedback architecture, the CLC406 offers a gain range of ±1 to ±10 while providing stable, oscillation free operation without external compensation, even at unity gain.

With its exceptional differential gain and phase, typically 0.02% and 0.02° at 3.58MHz, the CLC406 is designed to meet the performance and cost requirements of high volume composite video applications. The CLC406’s large signal bandwidth, high slew rate and high drive capability are features well suited for RGB video applications.

Providing a 12ns settling time to 0.05% (1/2 LSB in 10-bit systems) and -68/-75dBc 2nd/3rd harmonic distortion (2Vpp at 10MHz, RI=1kΩ), the CLC406 is an excellent choice as a buffer or driver for high speed A/D and D/A converter systems.

Commercial remote sensing applications and battery powered radio transceivers requiring a high performance, low power amplifier will find the CLC406 to be an attractive, cost-effective solution.

Constructioned using an advanced, complementary bipolar process and Comlinear’s proven current feedback architectures, the CLC406 is available in several versions to meet a variety of requirements.

Contact factory for other packages. DESC SMD number, 5962-92004.

Features (typical):
- 160MHz small signal bandwidth
- 50mW power (±5V supplies)
- 0.02%/0.02° differential gain/phase
- 12ns settling to 0.05%
- 1500V/µs slew rate
- 2.2ns rise and fall time (2Vpp)
- 70mA output current

Contact factory for complete die information.

Comlinear reserves the right to change specifications without notice.
The current feedback topology yields an inherently high slew rate. The dominant slew rate limiting mechanism is the onset of slew limiting, the buffer stage to the inverting inputs. Using a slew enhancement circuit the unity gain buffer used internally from the non-inverting amplifiers is necessary to maintain a fixed desired output swing. As the output signal swing is increased, the slew rates will decrease when operating the CLC406 at lower non-inverting gains due to the increasing signal swing through the buffer stage which is necessary to maintain a fixed desired output swing. Conversely, slew rates are generally higher and relatively insensitive to gain setting for inverting gain operation.

Slew Rate and Harmonic Distortion
The current feedback topology yields an inherently high slew rate amplifier. For this reason the CLC406 behaves differently in bandwidth between 2Vpp and 5Vpp outputs. The dominant slew rate limiting mechanism is the unity gain buffer used internally from the non-inverting to the inverting inputs. Using a slew enhancement circuit to sense the onset of slew limiting, the buffer stage momentarily increases the quiescent current to handle high slew requirements. Slew rates will decrease when operating the CLC406 at lower non-inverting gains due to the increasing signal swing through the buffer stage which is necessary to maintain a fixed desired output swing. Conversely, slew rates are generally higher and relatively insensitive to gain setting for inverting gain operation. An additional discussion of slew rates can be found in the CLC404 data sheet.

As the output signal swing is increased, the slew enhancement circuit found in the buffer stage acts to suppress harmonic distortions. This is one reason the CLC406 does not exhibit a simple relationship between output power and distortion. For example, the 2-tone, 3rd order spurious plot shows the spurious level to remain nearly constant over test tone power. For this reason the CLC406 does not exhibit an intercept type performance where the relative spurious levels change at twice the rate of the test tone power.

Differential Gain and Phase
Differential gain and phase performance specifications are common to composite video distribution applications. These specifications refer to the change in small signal gain and phase of the color subcarrier frequency (4.43MHz for PAL composite video) as the amplifier output is swept over a range of DC voltages. For this test only, the CLC406 is specified at a gain of +2 while connected to one or more doubly terminated 75Ω loads. Application Note OA-08 provides an additional discussion of differential gain and phase measurements.

Non-inverting Source Impedance
For best operation, the DC source impedance looking out of the non-inverting input should be less than 3kΩ but greater than 20Ω. Parasitic self oscillations may occur in the input transistors if the DC source impedance is out of this range. This impedance also acts as the gain for the non-inverting input bias and noise currents and therefore can become troublesome for high values of DC source impedance. The inverting configuration of Figure 2 shows a 25Ω resistor to ground on the non-inverting input which insures stability but does not provide bias current cancellation. The input bias currents are unrelated for a current feedback amplifier which eliminates the need for source impedance matching to achieve bias current cancellation.

DC Accuracy and Noise
Figure 3 shows an example of the output offset voltage computation. The calculation is developed using typical bias current and offset voltage specifications at 25°C, a gain (Av) of +6 and a non-inverting source impedance (Rin) of 25Ω.

Improved offset output voltage is possible using the composite circuits shown in Application Note OA-07. The total output offset noise is computed in a similar fashion to the output offset voltage. Using the input offset noise voltage and the two input noise currents, the total output offset noise is developed through the same gain equations for each term but combined as the square root of the sum of squared contributing elements. Application Note OA-12 provides a more detailed discussion of noise calculations for current feedback amplifiers.

Printed Circuit Layout
As with any high speed component, a careful attention to the board layout is necessary for optimum performance. Of particular importance is the careful control of parasitic capacitances on the output pin. As the output impedance plot shows, the closed loop output for the CLC406 eventually becomes inductive as the loop gain rolls off with increasing frequency. Direct capacitive loading on the output pin can quickly lead to peaking in the frequency response, overshoot in the pulse response, ringing or even sustained oscillations. The "Suggested Series Rin vs. C" plot should be used as a starting point when a capacitive load must be driven.

Evaluation boards (part number 730013 for through-hole and 730027 for SOIC) for the CLC406 are available. Further layout suggestions can be found in Application Note OA-15.
APPLICATIONS:
- flash A/D driver
- D/A transimpedance buffer
- wide dynamic range IF amp
- radar/communication receivers
- DDS post-amps
- wideband inverting summer
- line driver

DESCRIPTION

The CLC409 is a very wideband, DC coupled monolithic operational amplifier designed specifically for wide dynamic range systems requiring exceptional signal fidelity. Benefitting from Comlinear's current feedback architecture, the CLC409 offers a gain range of ±1 to ±10 while providing stable, oscillation free operation without external compensation, even at unity gain.

With its 350MHz small signal bandwidth (V_{out}=2V_{pp}), 10-bit distortion levels through 20MHz (R_L=1000), 8-bit distortion levels through 60MHz, 2.2nV/\sqrt{Hz} input referred noise and 13.5mA supply current, the CLC409 is the ideal driver or buffer for high speed flash A/D and D/A converters.

Wide dynamic range systems such as radar and communication receivers requiring a wideband amplifier offering exceptional signal purity will find the CLC409's low input referred noise and low harmonic and intermodulation distortion make it an attractive high speed solution.

Constructed using an advanced, complimentary bipolar process and Comlinear's proven current feedback architecture, the CLC409 is available in several versions to meet a variety of requirements.

3 – 77
The current feedback op amp, and hence the frequency different R value will limit feedback resistor. Using Feedback Resistor performance by using the current feedback harmonic distortion while driving very demanding resistive pioneered by CLC409 excessive ringing in the amplifier or capacitive supplies. The 2-tone, 3rd-order spurious full frequency. The introduced by the converter performance, (where the lowest page. The at a 2X rate vs. the test tone powers), due to an dissipating spurious distortions shown on the previous page. This feature enhances the distortion much higher quiescent applied directly amplifier. Figure 3 shows a power bandwidth enhancement circuit that boosts the full frequency bandwidth to match that of CLC409 excellent pulse. This is an available non-inverting gain circuit recommended inverting gain circuit dependence, however, in driving the capacitive input of an ADC. There is an option to increase R_s', bandlimiting at the ADC input for either noise or Nyquist bandlimiting purposes. Increasing R_s too much, however, can induce an unacceptably large input glitch due to switching transients coupling through from the convert signal. Also, C_in is oftentimes a voltage dependent capacitance. This input impedance non-linearity will induce distortion terms that will increase as R_s is increased. Only slight adjustments up or down from the recommended R_s value should therefore be attempted in optimizing system performance.

DC Accuracy and Noise
The CLC409 offers an improved offset voltage over the pin compatible CLC400 low gain amplifier. The offset adjustment available on the CLC400 was therefore not included in this part. Figure 4 shows the output offset computation equation for the non-inverting configuration with an example using the typical bias current and offset specifications for A_v = 2.

Output Offset
\[ V_o = \pm \frac{I_{in}R_s \pm V_{in}}{1 + R/R_g} \pm I_{in}R_i \]

Example Computation for A_v = 2, R_s = 250Ω, R_in = 25Ω: \[ V_o = (\pm 10\mu A(25Ω) \pm 0.5mV)2 \pm 10\mu A(250Ω) = \pm 3.25mV \]

Figure 4: Output DC Offset Calculation
This low output offset voltage is a marked improvement over earlier very high speed amplifiers. Further improvement in the output offset voltage and drift is possible using the composite amplifiers described in Application Note OA-7.

The two input bias currents are physically unrelated in both magnitude and polarity for the current feedback topology. It is not possible, therefore, to cancel their effects by matching the source impedance for the two inputs (as is commonly done for matched input bias current devices).

The total output noise is computed in a similar fashion to output offset voltage. Using the input noise voltage and two input noise currents, the output noise is developed through the same gain equations for each term but combined as the square root of the sum of squared contributing elements. See Application Note OA-12 for a full discussion of noise calculations for current feedback amplifiers.

Printed Circuit Layout
As with any high speed component, a careful attention to the board layout is necessary for optimum performance. Evaluation PC boards (part number 730013 for through-hole and 730027 for SOIC) for the CLC409 are available. This additional supply bypassing capacitor, C_sn, can easily be added to the board if desired. Further layout suggestions can be found in Application Note OA-15.
Fast Settling, Video Op Amp with Disable

CLC410

APPLICATIONS:
- video switching and distribution
- analog bus driving (with disable)
- low power “standby” using disable
- fast, precision A/D conversion
- D/A current-to-voltage conversion
- IF processors
- high-speed communications

DESCRIPTION:
The current-feedback CLC410 is a fast-settling, wideband, monolithic op amp with fast disable/enable feature. Designed for low-gain applications (Av = ± 1 to ± 8), the CLC410 consumes only 160mW of power (180mW max) yet provides a 3dB bandwidth of 200MHz (Av = +2) and 0.05% settling in 12ns (15ns max). Plus, the disable feature provides fast turn-on (100ns) and turn-off (200ns). In addition, the CLC410 offers both high performance and stability without compensation — even at a gain of +1.

The CLC410 provides a simple, high-performance solution for video switching and distribution applications, especially where analog buses benefit from use of the disable function to “multiplex” signals onto the bus. Differential gain/phase of 0.01% is available in several versions to meet a variety of requirements. A three-letter suffix determines the version:

CLC410AJP -40°C to +85°C 8-pin plastic DIP
CLC410AJE -40°C to +85°C 8-pin plastic SOIC
CLC410AIB -40°C to +85°C 8-pin hermetic CERDIP
CLC410ABB -55°C to +125°C 8-pin hermetic CERDIP
CLC410ALC -55°C to +125°C dice
CLC410AMC -55°C to +125°C dice qualified to Method 5008, MIL-STD-883, Level B

The CLC410 is available in several versions to meet a variety of requirements. A three-letter suffix determines the version:

Comlinear reserves the right to change specifications without notice.

Figure 1: recommended non-inverting gain circuit

For optimum performance, \( R_f \) and \( R_g \) should be low-inductance, low-capacitance resistors.

(Pin designations are for DIP versions.)

Figure 2: recommended inverting gain circuit

For optimum performance, \( R_f \) and \( R_g \) should be low-inductance, low-capacitance resistors.

(Pin designations are for DIP versions.)
Enable/Disable Operation
The CLC410 has an enable/disable feature that is useful for conserving power and for multiplexing the outputs of several amplifiers onto an analog bus (figure 3A). Disabling an amplifier while not in use reduces power supply current and the output and inverting input pins become a high impedance.

Pin 8, the DIS pin, can be driven from either open-collector TTL or from 5V CMOS. A logic low disables the amplifier and an internal 15KΩ pull-up resistor ensures that the amplifier is enabled if pin 8 is not connected (figure 4). Both TTL and 5V CMOS logic are guaranteed to drive a high enough high-level output voltage (V_{OH}) to ensure that the CLC410 is enabled. Whichever type used, “break-before-make” operation should be established when outputs of several amplifiers are connected together. This is important for avoiding large, transient currents flowing between amplifiers when two or more are simultaneously enabled. Typically, proper operation is ensured if all the amplifiers are driven from the same decoder integrated circuit because logic output rise times tend to be longer than fall times. As a result, the amplifier being disabled will reach the 2V threshold sooner than the amplifier being enabled (see t₀ of figure 3B timing diagram).

During disable, supply current drops to approximately 4mA and the inverting input and output pin impedances become 200KΩ || 0.5pF each. The total impedance that a disabled amplifier and its associated feedback network presents to the analog bus is determined from figure 5. For example, at a non-inverting gain of 1, the output impedance at video frequencies is 100KΩ || 1pF since the 250Ω feedback resistor is a negligible impedance. Similarly, output impedance is 500Ω || 0.5pF at a non-inverting gain of 2 (with R_f = R_g = 250Ω).

Differential Gain and Phase
Plots on the preceding page illustrate the differential gain and phase performance of the CLC410 at both 3.58 and 4.43MHz. Application Note OA-08 presents a measurement technique for measuring the very low differential gain and phase of the CLC410. Observe that the gain and phase errors remain low even as the output loading increases, making the device attractive for driving multiple video outputs.

Understanding the Loop Gain
The CLC410 is a current-feedback op amp. Referring to the equivalent circuit of figure 6, any current flowing in the inverting input is amplified to a voltage at the output through the transimpedance gain shown below. This Z(s) is analogous to the open-loop gain of a voltage feedback amplifier.

Developing the non-inverting frequency response for the topology of Figure 3 yields:

\[
\frac{V_o}{V_i} = \frac{1 + R_f / R_g}{1 - 1 / LG} \quad \text{eq. (1)}
\]

where LG is the loop gain defined by,

\[
LG = \frac{Z(s)}{R_i} \cdot \frac{1}{1 + Z_f / (R_i | R_g)} \quad \text{eq. (2)}
\]

Equation 1 has a form identical to that for a voltage feedback amplifier with the differences occurring in the LG expression, eq. 2. For an idealized treatment, set Z_f = 0 which results in a very simple LG = Z(s) / R_i (Derivation of the transfer function for the case where Z_f = 0 is given in the next page.)
Application Note AN300-1.) Using the Z(s) (open-loop transimpedance gain) plot shown on the previous page and dividing by the recommended $R_t = 250\Omega$, yields a large loop gain at DC. As a result, equation 1 shows that the closed-loop gain at DC is very close to $(1 + R_t/R_g)$.

![Figure 6: current feedback topology](image)

At higher frequencies, the roll-off of Z(s) determines the closed-loop frequency response which, ideally, is dependent only on $R_t$. The specifications reported on the previous pages are therefore valid only for the specified $R_t = 250\Omega$. Increasing $R_t$ from 250Ω will decrease the loop gain and bandwidth, while decreasing it will increase the loop gain possibly leading to inadequate phase margin and closed-loop peaking. Conversely, fixing $R_t$ will hold the frequency response constant while the closed-loop gain can be adjusted using $R_g$.

The CLC410 differs from this idealized analysis to the extent that the inverting input impedance is finite. With the low quiescent power of the CLC410, $Z_i = 50\Omega$ leading to a drop in loop gain and bandwidth at high gain settings, as given by equation 2. The second term in equation 2 accounts for the division in feedback current that occurs between $Z_i$ and $R_{in}$ at the inverting node of the CLC410. This decrease in bandwidth can be circumvented as described in “Increasing Bandwidth at High Gains.” Also see “Current Feedback Amplifiers” in the Comlinear Databook for a thorough discussion of current feedback op amps.

### Increasing Bandwidth At High Gains

Bandwidth may be increased at high closed-loop gains by adjusting $R_t$ and $R_g$ to make up for the losses in loop gain that occur at these high gain settings due to current division at the inverting input. An approximate relationship may be obtained by holding the LG expression constant as the gain is changed from the design point used in the specifications (that is, $R_t = 250\Omega$ and $R_g = 250\Omega$). For the CLC410 this gives,

$$R_t = 350 - 50A_v \quad \text{and} \quad R_g = \frac{350 - 50A_v}{A_v - 1} \quad \text{eq. (3)}$$

where $A_v$ is the non-inverting gain. Note that with $A_v = +2$ we get the specified $R_t = 250\Omega$, while at higher gains, a lower value gives stable performance with improved bandwidth.

### DC Accuracy and Noise

Since the two inputs for the CLC410 are quite dissimilar, the noise and offset error performance differs somewhat from that of a standard differential input amplifier. Specifically, the inverting input current noise is much larger than the non-inverting current noise. Also the two input bias currents are physically unrelated rendering bias current cancellation through matching of the inverting and non-inverting pin resistors ineffective.

In equation 4, the output offset is the algebraic sum of the equivalent input voltage and current sources that influence DC operation. Output noise is determined similarly except that a root-sum-of-squares replaces the algebraic sum. $R_s$ is the non-inverting pin resistance.

$$\text{Output Offset } V_o = \pm IB \times (1 + R_t/R_g) \pm \text{eq. (4)}$$

An important observation is that for fixed $R_t$ offsets as referred to the input improve as the gain is increased (divide all terms by $1 + R_t/R_g$). A similar result is obtained for noise where noise figure improves as gain increases.

The input noise plot shown in the CLC400 datasheet applies equally as well to the CLC410.

### capacitive Feedback

Capacitive feedback should not be used with the CLC410 because of the potential for loop instability. See Application Note OA-7 for active filter realizations with the CLC410.

### Offset Adjustment Pin

Pin 1 can be connected to a potentiometer as shown in Fig. 1 and used to adjust the input offset of the CLC410. Full range adjustment of ±5V on pin 1 will yield a ±10mV input offset adjustment range. Pin 1 should always be bypassed to ground with a ceramic capacitor located close to the package for best settling performance.

### Printed Circuit Layout

As with any high frequency device, a good PCB layout will enhance performance. Ground plane construction and good power supply bypassing close to the package are critical to achieving full performance. In the non-inverting configuration, the amplifier is sensitive to stray capacitance to ground at the inverting input. Hence, the inverting node connections should be small with minimal coupling to the ground plane. Shunt capacitance across the feedback resistor should not be used to compensate for this effect.

Parasitic or load capacitance directly on the output will introduce additional phase shift in the loop degrading the loop phase margin and leading to frequency response peaking. A small series resistor before the capacitance effectively decouples this effect. The graphs on the preceding page illustrate the required resistor value and resulting performance vs. capacitance.

Precision buffered resistors (PRP8351 series from Precision Resistive Products) with low parasitic reactances were used to develop the data sheet specifications. Precision carbon composition resistors will also yield excellent results. Standard spirally-trimmed RN55D metal film resistors will work with a slight decrease in bandwidth due to their reactive nature at high frequencies.

Evaluation PC boards (part number 730013 for through-hole and 730027 for SOIC) for the CLC410 are available.
APPLICATIONS:
- HDTV amplifier
- video line driver
- high-speed analog bus driver
- video signal multiplexer
- DAC output buffer

DESCRIPTION
The CLC411 combines a state-of-the-art complementary bipolar process with Comlinear’s patented current-feedback architecture to provide a very high-speed op amp operating from ±15V supplies. Drawing only 11mA quiescent current, the CLC411 provides a 200MHz small signal bandwidth and a 2300V/μs slew rate while delivering a continuous 70mA current output with ±4.5V output swing. The CLC411’s high-speed performance includes a 15ns settling time to 0.1% (2V step) and a 2.3ns rise and fall time (6V step).

The CLC411 is designed to meet the requirements of professional broadcast video systems including composite video and high definition television. The CLC411 exceeds the HDTV standard for gain flatness to 30MHz with its ±0.05dB flat frequency response and exceeds composite video standards with its very low differential gain and phase errors of 0.02%, 0.03°. The CLC411 is the op amp of choice for all video systems requiring upward compatibility from NTSC and PAL to HDTV.

The CLC411 features a very fast disable/enable (10ns/55ns) allowing the multiplexing of high-speed signals onto an analog bus through the common output connections of multiple CLC411’s. Using the same signal source to drive disable/enable pins is easy since “break-before-make” is guaranteed.

The CLC411 is available in several versions.

3 – 86
Description
The CLC411 is a high-speed current-feedback operational amplifier which operates from ±15V power supplies. The external supplies (±VCc) are regulated to lower voltages internally. The amplifier itself sees approximately ±6.5V rails. Thus the device yields performance comparable to Comlinear's ±5V devices, but with higher supply voltages. There is no degradation in rated specifications when the CLC411 is operated from ±12V. A slight reduction in bandwidth will be observed with ±10V supplies. Operation at less than ±10V is not recommended.

A block diagram of the amplifier and regulator topology is shown in Figure 3, "CLC411 Equivalent Circuit." The regulators derive their reference voltage from an internal floating zener voltage source. External control of the zener reference pins can be used to level-shift amplifier operation which is discussed in detail in the section entitled “Extending Input/Output Range with VR.”

Power Supply Decoupling
There are four pins associated with the power supplies. The VCc pins (4,7) are the external supply voltages. The VR pins (5,1) are connected to internal reference nodes. Figures 1 and 2, “Recommended Non-inverting Gain Circuit” and “Recommended Inverting Gain Circuit” show the recommended supply decoupling scheme with four ceramic and two electrolytic capacitors. The ceramic capacitors must be placed immediately adjacent to the device pins and connected directly to a good low-inductance ground plane. Bypassing the VR pins will reduce high frequency noise (>10MHz) in the amplifier. If this noise is not a concern these capacitors may be eliminated.

Differential Gain and Phase
The differential gain and phase errors of the CLC411 driving one doubly-terminated video load (RL=150Ω) are specified and guaranteed in the “Electrical Characteristics” table. The “Typical Performance” plot, “Differential Gain and Phase (4.43MHz)” shows the differential gain and phase performance of the CLC411 when driving from one to four video loads. Application note OA-08, “Differential Gain and Phase for Composite Video Systems,” describes in detail the techniques used to measure differential gain and phase.

Feedback Resistor
The loop gain and frequency response for a current-feedback operational amplifier is determined largely by the feedback resistor, Rf. The electrical characteristics and typical performance plots contained within the datasheet, unless otherwise stated, specify an Rf of 301Ω, a gain of +2V/V and operation with ±15V power supplies. The frequency response at different gain settings and supply voltages can be optimized by selecting a different value of Rf. Generally, lowering Rf will peak the frequency response and extend the bandwidth while increasing its value will roll off the response. For unity-gain voltage follower circuits, a non-zero Rf must be used with current-feedback operational loops.
amplifiers such as the CLC411. Application note OA-13, "Current-Feedback Loop-Gain Analysis and Performance Enhancements," explains the ramifications of R₁ and how to use it to tailor the desired frequency response with respect to gain. The equations found in the application note should be considered as a starting point for the selection of R₁. The equations do not factor in the effects of parasitic capacitance found on the inverting input, the output nor across the feedback resistor. Equations in OA-13 require values for R₁ (301Ω), Av (+2) and Rᵢ (inverting input resistance, 50Ω). Combining these values yields a Zₛ* (optimum feedback transimpedance) of 400Ω. Figure 4 entitled "Recommended R₁ vs. Gain" will enable the selection of the feedback resistor that provides a maximally flat frequency response for the CLC411 over its gain range. The linear portion of the two curves (i.e. Aᵥ>4) results from the limitation on Rᵢ (i.e. Rᵢ ≥50Ω).

Enable/Disable Operation
The disable feature allows the outputs of several CLC411 devices to be connected onto a common analog bus forming a high-speed analog multiplexer. When disabled, the output and inverting inputs of the CLC411 become high impedances. The disable pin has an internal pull-up resistor which is pulled-up to an internal voltage, not to the external supply. The CLC411 is enabled when pin 8 is left open or pulled-up to ≥+7V and disabled when grounded or pulled below +3V. CMOS logic devices are necessary to drive the disable pin. For example, CMOS logic with V_DD ≥+7V will guarantee proper operation over temperature. TTL voltage levels are inadequate for controlling the disable feature.

For faster enable/disable operation than 15V CMOS logic devices will allow, the circuit of Figure 5 is recommended. A fast four-transistor comparator, Figure 5A, interfaces between the CLC411 DISABLE pin and several standard logic families. This circuit has a differential input between the bases of Q1 and Q2. As such it may be driven directly from differential ECL logic, as in shown in Figure 5B. Single-ended logic families may also be used by establishing an appropriate threshold voltage on the Vₜₙ₉ input, the base of Q2. Figures 5C and 5D illustrate a single-ended ECL and TTL interface respectively. The Disable input, the base of Q1, is driven above and below the threshold, Vₜₙ₉.

Fastest switching speeds result when the differential voltage between the bases of Q1 and Q2 is kept to less than one volt. Single-ended ECL, Figure 5C, maintains this desired maximum differential input voltage. TTL and CMOS have higher Vₜ₉₉ to Vₜ₉₉ low excursions. The
circuit of figure 5D will ensure the voltage applied between the bases of Q1 and Q2 does not cause excessive switching delays in the CLC411. Under the above proscribed four-transistor interface, all variations were evaluated with approximately 1ns rise and fall times which produced switching speeds equivalent to the rated disable/enable switching times found in the "CLC411 Electrical Characteristics" table.

A general multiplexer configuration using several CLC411s is illustrated in figure 6, where a typical 8-to-1 digital mux is used to control the switching operation of the paralleled CLC411s. Since "break-before-make" is a guaranteed specification of the CLC411 this configuration works nicely. Notice the buffers used in driving the disable pins of the CLC411s. These buffers may be 15V CMOS logic devices mentioned previously or any variation of the four-transistor comparator illustrated above.

Extending Input/Output Range with \( V_r \)

As can be seen in Figure 3, the magnitude of the internal regulated supply voltages is fixed by \( V_r \). In normal operation, with \( \pm 15V \) external supplies, \( +V_r \) is nominally \( +9V \) when left floating. CMIR (common mode input range) and VO (output voltage range, no load) are specified under these conditions. These parameters implicitly have 0V as their midpoint, i.e. the VO range is \( \pm 6V \), centered at 0V.

An external voltage source can be applied to \( +V_r \) to shift the range of the input/output voltages. For example, if it were desired to move the positive VO range from \( +6V \) to a \( +9V \) maximum in unipolar operation, Figure 7, "DC Parameters as a Function of \( +V_r \)" is used to determine the required supply and \( +V_r \) voltages. Referring to Figure 7, locate the point on the \( +V_{max} \) line where the ordinate is \( +9V \). Draw a vertical line from this point intersecting the other lines in the graph. The circuit voltages are the ordinates of these intersections. For this example these points are shown in the graph as solid dots. The required voltage sources are \( +V_r = +12V, +V_{cc} = +12V, -V_{cc} = -12V \). When these supply and reference voltages are applied, the range for VO is \( -3V \) to \( +9V \), and CMIR ranges from \( -1V \) to \( +7V \). The difference between the minimum and maximum voltages is constant, i.e. \( 12V \) for VO, only the midpoint has been shifted, i.e. from 0V to \( +3V \) for VO.

Note that in this example the \( -V_r \) pin has been left open (or bypassed to reduce high-frequency noise). The difference between \( +V_r \) and \( -V_r \) is fixed by \( V_r \). A level-shifting voltage can be applied to only one of the reference pins, not both. If extended operation were needed in the negative direction, Figure 4 may be used by changing the signs, and applying the resultant negative voltage to the \( -V_r \) pin. It is recommended that \( +V_r \) be used for positive shifts, and \( -V_r \) for negative shifts of input/output voltage range.

Printed Circuit Layout & Evaluation Board

Refer to application note OA-15, "Frequent Faux Pas in Applying Wideband Current Feedback Amplifiers," for board layout guidelines and construction techniques. Two very important points to consider before creating a layout which are found in the above application note are worth reiteration. First the input and output pins are sensitive to parasitic capacitances. These parasitic capacitances can cause frequency-response peaking or sustained oscillation. To minimize the adverse effect of parasitic capacitances, the ground plane should be removed from those pins to a distance of at least 0.25" Second, leads should be kept as short as possible in the finished layout. In particular, the feedback resistor should have its shortest lead on the inverting input side of the CLC411. The output is less sensitive to parasitic capacitance and therefore can drive the longer of the two feedback resistor connections. The evaluation board available for the CLC411 (part #730013 for through-hole packages, 730027 for SO-8) may be used as a reference for proper board layout. Application schematics for this evaluation board are in the product accessories section of the Comlinear databook.
APPLICATIONS:
• HDTV, NTSC & PAL video systems
• video switching and distribution
• multi-channel tele-communications amplifier
• wideband active filters
• cable drivers
• dc coupled single-to-differential conversions

DESCRIPTION
The CLC412 combines a high-speed complementary bi-polar process with Comlinear's proprietary current-feedback topology to produce a very high-speed dual op amp. The CLC412 provides a 250MHz -3dB bandwidth (SOIC) at a gain of +2 and a 1300V/µs slew rate while consuming only 50mW per amplifier from ±5V supplies.

The CLC412 offers exceptional video performance with its 0.01% and 0.02% differential gain and phase errors for NTSC and PAL video signals while driving one back terminated 75Ω load. The CLC412 also offers flat gain response to 30MHz of 0.1dB and high channel-channel isolation at 10MHz of -82dB (SOIC), -68dB (PDIP). Additionally, each amplifier delivers a 70mA continuous output current (RL=100Ω). This level of performance makes the CLC412 an ideal dual op amp for many professional video applications.

The CLC412 is also well suited for wideband signal conditioning active filters such as anti-aliasing filters for high-speed A/D converters. Its small 8-pin SOIC package, low power requirement and low noise and distortion allow the CLC412 to serve portable RF applications such as tele-video/communications.

The CLC412 is available in the following versions.

- CLC412AJP -40°C to +85°C 8-pin Plastic DIP
- CLC412AJE -40°C to +85°C 8-pin Plastic SOIC
- CLC412AIB -40°C to +85°C 8-pin CERDIP
- CLC412A8B -55°C to +125°C 8-pin CERDIP, MIL-STD-883, Level B
- CLC412A8L-2 -55°C to +125°C 20-pin LCC, MIL-STD-883, Level B
- CLC412ALC -55°C to +125°C dice, MIL-STD-883, Level B
- CLC412AMC -55°C to +125°C dice, MIL-STD-883, Level B

Contact factory for other packages and DESC SMD number.

FEAT URES (typical):
• 250MHz -3dB bandwidth (SOIC)
• 0.1dB gain flatness to 30MHz
• 5mA per channel quiescent current
• 0.01%, 0.02% differential gain, phase
• -82dBc channel isolation @ 10MHz (SOIC)
• 1300V/µs slew rate
• 70mA continuous output current
• gain range ±1 to ±10V/V

APPplications:
- composite video distribution amps
- HDTV amplifiers
- RGB-video amplifiers
- CCD signal processing
- active filters
- instrumentation diff amps
- general purpose high density requirements

DESCRIPTION:
The CLC414 is a low-power, quad, monolithic operational amplifier designed for intermediate-gain applications where power and cost per channel are of primary concern. Benefiting from Comlinear's current feedback architecture, the CLC414 offers a gain range of ±1 to ±10 while providing stable, oscillation-free operation without external compensation, even at unity gain.

Operating from ±5V supplies, the CLC414 consumes only 25mW of power per channel, yet maintains a 90MHz small-signal bandwidth and a 1000V/µs slew rate. The CLC414 also provides wide channel isolation with its 70dB crosstalk (input referred at 5MHz). Applications requiring a high-density solution to high-speed amplification such as active filters and instrumentation diff amps will benefit from the CLC414's four integrated, wideband op amps in one 14-pin package.

Commercial remote-sensing applications and battery-powered radio transceivers requiring high-performance, low-power amplifiers will find the CLC414 to be an attractive, cost-effective solution. In composite video switching and distribution applications, the CLC414 offers differential gain and phase performance of 0.1%, 0.12% at 3.58MHz.

The lower power CLC414 and the wideband CLC415 are quad versions of the CLC406. Both of these quads afford the designer lower power consumption and lower cost per channel with the additional benefit of requiring less board space per amplifier.

Constructed using an advanced, complementary bipolar process and Comlinear's proven current feedback architectures, the CLC414 is available in several versions to meet a variety of requirements.

CLC414AJP -40°C to +85°C 14-pin plastic DIP
CLC414AJE -40°C to +85°C 14-pin plastic SOIC

Note 1: Gain flatness tests performed from 0.1MHz.
Feedback Resistor

The CLC414 achieves its exceptional AC performance while requiring very low quiescent power by using the current feedback topology and an internal slew rate enhancement circuit. The loop gain and frequency response for a current feedback op amp is predominantly set by the feedback resistor value. The CLC414 is optimized for a gain of +6 to use a 500Ω feedback resistor (use a 1kΩ Rf for maximally flat response at a gain of +2). Using lower values can lead to excessive ringing in the pulse response while a higher value will limit the bandwidth. Application Note OA-13 provides a more detailed discussion of choosing a feedback resistor. The equations found in this application note are to be considered a starting point for the determination of Rf at any gain. The value of input impedance for the CLC414 is approximately 2500Ω. These equations do not account for parasitic capacitance at the inverting input nor across Rf. The plot found below entitled “Recommended Rf vs. Gain” offers values of Rf which will optimize the frequency response of the CLC414 over its ±1 to ±10 gain range. Unlike voltage feedback, current feedback op amps require a non-zero Rf for unity gain followers.

Unused Amplifiers

It is recommended that any unused amplifiers in the quad package be connected as unity gain followers (Rf = 500Ω) with the non-inverting input tied to ground through a 500Ω resistor.

Slew Rate and Harmonic Distortion

Please see the application information for the CLC406.

Differential Gain and Phase

Differential gain and phase performance specifications are common to composite video distribution applications. These specifications refer to the change in small signal gain and phase of the color subcarrier frequency (4.43 MHz for PAL composite video) as the amplifier output is swept over a range of DC voltages. Application Note OA-08 provides an additional discussion of differential gain and phase measurements.

Non-inverting Source Impedance

For best operation, the DC source impedance looking out of the non-inverting input should be less than 3kΩ but greater than 20Ω. Parasitic self oscillations may occur in the input transistors if the DC source impedance is out of this range. This impedance also acts as the gain for the non-inverting input bias and noise currents and therefore can become troublesome for high values of DC source impedance. The inverting configuration of Figure 2 shows a 250Ω resistor to ground on the non-inverting input which insures stability but does not provide bias current cancellation. The input bias currents are unrelated for a current feedback amplifier which eliminates the need for source impedance matching to achieve bias current cancellation.

DC Accuracy and Noise Calculation

Please refer to the application information for the CLC406.

Crosstalk

In any multi-channel integrated circuit there is an undesirable tendency for the signal in one channel to couple with and reproduce itself in the output of another channel. This effect is referred to as crosstalk. Crosstalk is expressed as channel separation or channel isolation which indicates the magnitude of this undesirable effect. This effect is measured by driving one or more channels and observing the output of the other undriven channel(s). The CLC414 plot page offers two different graphs detailing the effect of crosstalk over frequency. One plot entitled “All-HOSTILE Crosstalk Isolation” graphs all-hostile input-referred crosstalk. All-hostile crosstalk refers to the condition where three channels are driven simultaneously while observing the output of the undriven fourth channel. Input-referred implies that crosstalk is directly affected by gain and therefore a higher gain increases the crosstalk effect by a factor equal to that gain setting. The plot entitled “Most Susceptible Channel-to-Channel Pulse Coupling” describes the effect of crosstalk when one channel is driven with a 2Vpp pulse while the output of the most affected channel is observed.

Printed Circuit Layout

As with any high speed component, a careful attention to the board layout is necessary for optimum performance. Of particular importance is the careful control of parasitic capacitances on the output pin. As the output impedance plot shows, the closed loop output for the CLC414 eventually becomes inductive as the loop gain rolls off with increasing frequency. Direct capacitive loading on the output pin can quickly lead to peakin in the frequency response, overshoot in the pulse response, ringing or even sustained oscillations. The “Settling Time vs. Capacitive Load” plot should be used as a starting point for the selection of a series output resistor when a capacitive load must be driven. A quad amplifier will require careful attention to signal routing in order to minimize the effects of crosstalk. Signal coupling through the power supplies can be reduced with bypass capacitors placed close to the device supply pins.

Evaluation Board

Evaluation PC boards (part number 730024 for through-hole and 730031 for SOIC) for the CLC414 are available.
APPLICATIONS:
- composite video distribution amps
- HDTV amplifiers
- RGB-video amplifiers
- CCD signal processing
- active filters
- instrumentation diff amps
- channelized EW

DESCRIPTION:
The CLC415 is a wideband, quad, monolithic operational amplifier designed for intermediate-gain applications where power and cost per channel are of primary concern. Benefitting from Comlinear's current feedback architecture, the CLC415 offers a gain range of ±1 to ±10 while providing stable, oscillation-free operation without external compensation, even at unity gain.

Operating from ±5V supplies, the CLC415 consumes only 50mW of power per channel, yet maintains a 160MHz small-signal bandwidth and a 1500V/µs slew rate. High density applications requiring an integrated solution will enjoy the CLC415's 70dB channel isolation (input referred @ 5MHz).

With its exceptional differential gain and phase, typically 0.03% and 0.03° @ 3.55MHz, the CLC415 is designed to meet the performance and cost per channel requirements of high volume composite video applications. The CLC415's large-signal bandwidth, high slew rate and high drive capability are features well suited for RGB-video applications.

The CLC415 is a quad version of the high speed CLC406 while the CLC414 is a lower power quad version of the same. Both of these quads afford the designer lower power consumption and lower cost per channel with the additional benefit of requiring less board space per amplifier.

Constructed using an advanced, complementary bipolar process and Comlinear's proven current feedback architectures, the CLC415 is available in several versions to meet a variety of requirements.

Contact factory for other packages. DESC SMD number 5962-93055.

FEATURES (typical):
- 160MHz small-signal bandwidth
- 5mA quiescent current per amplifier
- 70dB channel isolation @ 5MHz
- 0.03%/0.03° differential gain/phase
- 12ns settling to 0.1%
- 1500V/µs slew rate
- 2.0ns rise and fall time (2Vpp)
- 70mA output current per amplifier
INTRODUCTORY INFORMATION: specifications are based on the characteristics of a limited number of devices.

**Electrical Characteristics (A<sub>in</sub> = ±6 V, V<sub>cc</sub> = ±5 V, R<sub>L</sub> = 100 Ω, R<sub>l</sub> = 500 Ω)**

Feedback Resistor

The CLC415 achieves its exceptional AC performance while requiring very low quiescent power by using the current feedback topology and an internal slew rate enhancement circuit. The loop gain and frequency response for a current feedback op amp is predominantly set by the feedback resistor value. The CLC415 is optimized for a gain of +6 to use a 50Ω feedback resistor (use a 900Ω Rf, for maximally flat response at a gain of +2). Using lower values can lead to excessive ringing in the pulse response while a higher value will limit the bandwidth.

Application Note OA-13 provides a more detailed discussion of choosing a feedback resistor. The equations found in this application note are to be considered a starting point for the determination of Rf at any gain. The value of input impedance for the CLC415 is approximately 60Ω. These equations do not account for parasitic capacitance at the inverting input nor across Rf. The plot found below entitled “Recommended Rf vs. Gain” offers values of Rf which will optimize the frequency response of the CLC415 over its ±1 to ±10 gain range. Unlike voltage feedback, current feedback op amps require a non-zero Rf for unity gain followers.

Unused Amplifiers

It is recommended that any unused amplifiers in the quad package be connected as unity gain followers (Rf = 500Ω) with the non-inverting input tied to ground through a 50Ω resistor.

Slew Rate and Harmonic Distortion

Please see the application information for the CLC406.

Differential Gain and Phase

Differential gain and phase performance specifications are common to composite video distribution applications. These specifications refer to the change in small signal gain and phase of the color subcarrier frequency (4.43MHz for PAL composite video) as the amplifier output is swept over a range of DC voltages. Application Note OA-08 provides an additional discussion of differential gain and phase measurements.

Non-inverting Source Impedance

For best operation, the DC source impedance looking out of the non-inverting input should be less than 3kΩ but greater than 20Ω. Parasitic self oscillations may occur in the input transistors if the DC source impedance is out of this range. This impedance also acts as the gain for the non-inverting input bias and noise currents and therefore can become troublesome for high values of DC source impedance. The inverting configuration of Figure 2 shows a 25Ω resistor to ground on the non-inverting input which insures stability but does not provide bias current cancellation. The input bias currents are unrelated for a current feedback amplifier which eliminates the need for source impedance matching to achieve bias current cancellation.

DC Accuracy and Noise

Please refer to the application information section of the CLC406 for a discussion of output offset voltage and spot noise calculation.

Crosstalk

In any multi-channel integrated circuit there is an undesirable tendency for the signal in one channel to couple with and reproduce itself in the output of another channel. This effect is referred to as crosstalk. Crosstalk is expressed as channel separation or channel isolation which indicates the magnitude of this undesirable effect. This effect is measured by driving one or more channels and observing the output of the other undriven channel(s). The CLC415 plot page offers two different graphs detailing the effect of crosstalk over frequency. One plot entitled “All-Hostile Crosstalk Isolation” graphs all-hostile, input-referred crosstalk. All-hostile crosstalk refers to the condition where three channels are driven simultaneously while observing the output of the undriven fourth channel. Input-referred implies that crosstalk is directly affected by gain and therefore a higher gain increases the crosstalk effect by a factor equal to that gain setting. The plot entitled “Most Susceptible Channel-to-Channel Pulse Coupling” describes the effect of crosstalk when one channel is driven with a 2Vpp pulse while the output of the most affected channel is observed.

Printed Circuit Layout

As with any high speed component, a careful attention to the board layout is necessary for optimum performance. Of particular importance is the careful control of parasitic capacitances on the output pin. As the output impedance plot shows, the closed loop output for the CLC415 eventually becomes inductive as the loop gain rolls off with increasing frequency. Direct capacitive loading on the output pin can quickly lead to peaking in the frequency response, overshoot in the pulse response, ringing or even sustained oscillations. The “Settling Time vs. Capacitive Load” plot should be used as a starting point for the selection of a series output resistor when a capacitive load must be driven. A quad amplifier will require careful attention to signal routing in order to minimize the effects of crosstalk. Signal coupling through the power supplies can be reduced with bypass capacitors placed close to the device supply pins.

Evaluation Board

Evaluation PC boards (part number 730024 for through-hole and 730031 for SOIC) for the CLC415 are available.
APPLICA TIONS:
• active filters/integrators
• differential amplifiers
• pin diode receivers
• log amplifiers
• D/A converters
• photo multiplier amplifiers

The CLC420 is an operational amplifier designed for applications requiring matched inputs, integration or transimpedance amplification. Utilizing voltage feedback architecture, the CLC420 offers a 300MHz bandwidth, a 1100 V/\mu s slew rate and a 4mA supply current (power consumption of 40mW, ±5V supplies). Additional benefits of the CLC420B are a 0.5mV input offset voltage and a 4\mu V/°C temperature coefficient.

Applications such as differential amplifiers will benefit from 70dB common mode rejection ratio and an input offset current of 0.2\mu A. With its unity-gain stability, 2pA/\sqrt{Hz} current noise and 3\mu A of input bias current, the CLC420 is designed to meet the needs of filter applications and log amplifiers. The low input offset current and current noise, combined with a settling time of 18ns to 0.01% make the CLC420 ideal for D/A converters, pin diode receivers and photo multipliers amplifiers. All applications will find 70dB power supply rejection ratio attractive.

The CLC420 is available in several versions to meet a variety of requirements.

The very attractive for active feedback features. Gain bandwidth product closed-loop amplifiers, these errors can be reduced to a term. The noise gain of the circuit (for noise gains greater than 5). Unlike DC accuracy non-inverting and inverting input bias currents are matched and track over temperature, etc. As a result, by matching the resistance looking out of the two inputs, these errors can be reduced to a small offset current term.

Gain bandwidth product
Since the CLC420 is a voltage-feedback op-amp, closed-loop bandwidth is approximately equal to the gain-bandwidth product (typically 100MHz) divided by the noise gain of the circuit (for noise gains greater than 5). At lower noise gains, higher-order amplifier poles contribute to higher closed-loop bandwidth. At low gains use the frequency response performance plots given in the data sheet.

Another point to remember is that the closed-loop bandwidth is determined by the noise gain, not the signal gain of the circuit. Noise gain is the reciprocal of the attenuation in the feedback network enclosing the op amp. For example, a CLC420 setup as a non-inverting amplifier with a closed-loop gain of +1 (a noise gain of 1) has a 300MHz bandwidth. When used as an inverting amplifier with a gain of -1 (a noise gain of 2), the bandwidth is less, typically only 100MHz.

Full-power bandwidth, and slew-rate
The CLC420 combines exceptional full-power bandwidths (40MHz, $V_{OD}=5Vp$, $A_{v}=+1$) and slew rates (11000V/µs, $A_{v}=+1$) with low (40mW) power consumption. These attractive results are achieved by using slew-boosting circuitry to keep the slew rates high while consuming very little power.

In non-slew boosted amplifiers, full-power bandwidth can be easily determined from slew-rate measurements, but in slew-boosted amplifiers, such as the CLC420, you can't. For this reason we provide data for both.

Slew rate is also different for inverting and non-inverting configurations. This occurs because common-mode signal voltages are present in non-inverting circuits but absent in inverting circuits. Once again data is provided for both.

Transimpedance amplifier circuits
Low inverting, input current noise (2pA/√Hz) makes the CLC420 ideal for high-sensitivity transimpedance amplifier circuits for applications such as pin-diode optical receivers, and detectors in receiver IFs. However, feedback resistors 4kΩ or greater are required if feedback resistor noise current is going to be less than the input current noise contribution of the op-amp.

With feedback resistors this large, shunt capacitance on the inverting input of the op-amp (from the pin-diode, etc.) will unacceptably degrade phase margin causing frequency response peaking or oscillations. A small-valued capacitor shunting the feedback resistor solves this problem (Note: This approach does not work for a current-feedback op-amp configured for transimpedance applications). To determine the value of this capacitor, refer to the "Transimpedance BW vs. $R_f$ and $C_f$" plot.

For example, let's assume an optical transimpedance receiver is being developed. Total capacitance from the inverting input to ground, including the photodiode and strays is 5pF. A 5kΩ feedback resistor value has been determined to provide best dynamic range based on the responsibility of the photodiode and the range of incident optical powers, etc. From the "Transimpedance BW vs. $R_f$ and $C_f$" plot, using $C_f = 5pF$ it is determined from the two curves labeled $C_f = 5pF$, that $C_f = 1.5pF$ provides optimal compensation (no more than 0.5dB frequency response peaking) and a -3dB bandwidth of approximately 27MHz.

Printed circuit layout
As with any high frequency device, a good PCB layout will enhance performance. Ground plane construction and good power supply bypassing close to the package are critical to achieving full performance. The amplifier is sensitive to stray capacitance to ground at the output and inverting input: Node connections should be small with minimal coupling to the ground plane.

Parasitic or load capacitance directly on the output (pin 6) will introduce additional phase shift in the loop degrading the loop phase margin and leading to frequency response peaking. A small series resistor before this capacitance, if present, effectively decouples this effect. The graphs on the preceding page, "Settling Time vs. $C_L$", illustrate the required resistor value and resulting performance vs. capacitance.

Evaluation PC boards (part number 730013 for through-hole and 730027 for SOIC) for the CLC420 are available.
APLICATIONS:
- differential amplifier
- IF amplifier
- high-gain amplifier
- high-precision applications
- instrumentation amplifier
- low voltage-noise amplifier

DESCRIPTION
The CLC422 is a very high-speed operational amplifier employing a traditional voltage-feedback architecture and Comlinear's slew enhancement circuitry. Providing a 200MHz, -3dB bandwidth (Av = ±40) and a 2300V/µs slew rate, the CLC422 is designed for applications requiring very small, high-frequency signals. Since the CLC422 is not slew limited, there is little degradation in performance between small and large signal operation. At a non-inverting gain of 40, the CLC422 maintains a 200MHz, -3dB bandwidth for both 0.5Vpp and 5.0Vpp output voltages.

The CLC422 delivers precise performance with its excellent DC characteristics, such as a 0.8mV input offset voltage, 0.5µA input offset current and a 15µA input bias current. AC dynamic performance includes a rise/fall time of 2ns for both 0.5Vpp and 5.0Vpp output steps. Overshoot is typically 1% and settling time to 0.2% is 17ns.

The CLC422 is the ideal amplifier to extract very small, high-frequency signals from a noisy environment due to its high common mode rejection, extremely low input-voltage noise and high gain range. All these characteristics contribute to an excellent signal-to-noise ratio.

The high-gain CLC422 complements the unity-gain stable CLC420, both of which offer very high speeds using a traditional voltage-feedback architecture. The CLC422 is available in several versions to meet a variety of requirements.

Contact factory for other packages. DESC SMD number, 5962-91666.

FEATURES (typical):
- 200MHz, -3dB bandwidth (Av = ±40V/V)
- 2300V/µs slew rate
- 2.4nV/√Hz input voltage noise
- 0.8mV input offset voltage
- 4.5pA/√Hz input current noise
- 88dB common-mode rejection
- recommended gain range: ±30 to ±200V/V

APPLICATIONS:
- IF amplifier
- high-gain amplifier
- high-precision applications
- instrument amplifier
- low voltage-noise amplifier

**Description**

The CLC422 is a high-speed, slew-boosted, voltage-feedback amplifier designed for operation at gains of thirty or more. These features along with matched inputs, low input bias and noise currents, and excellent CMRR render the CLC422 very attractive for high-gain differential and instrumentation amplifiers, IF amplifiers, and applications requiring exceptional gain-bandwidth product.

**DC accuracy**

Unlike current-feedback amplifiers, voltage-feedback amplifiers have matched inputs. This means that the non-inverting and inverting input bias currents are well matched and track over temperature, etc. As a result, by matching the resistance looking out of the two inputs, these errors can be reduced to a small offset current term.

**Gain bandwidth product**

Since the CLC422 is a voltage-feedback op amp, closed-loop bandwidth is approximately equal to the gain-bandwidth product (typically 2GHz) divided by the noise gain (the reciprocal of the attenuation of the feedback network enclosing the op amp) of the circuit for noise gains greater than 100. At lower noise gains, higher-order amplifier poles contribute to higher closed-loop bandwidth. At lower gains use the frequency response performance plots given in the data sheet.

**Full-power bandwidth, and slew-rate**

Since the CLC422's slew-boosting circuitry prevents slew rate limiting, the full-power bandwidth is identical to the small-signal bandwidth. This device also sets a new standard for gain-bandwidth product in a monolithic voltage-feedback op amp (2GHz) while consuming a modest 170mW from ±5 volt supplies.

**Low-gain voltage stages and transimpedance amplifiers**

As a general rule, a CLC422 should only be used at gains greater than ±30. For lower gain stages and/or transimpedance amplifiers, other members of Comlinear's family of current and voltage-feedback amplifiers can provide superior performance.

However, in a few instances a CLC422 may provide somewhat better bandwidth or lower distortion at low frequencies (below 10MHz) than other amplifiers operating at comparable gains. To stabilize a CLC422 to gains lower than ±30 requires strict attention to distributed capacitances, layouts, and a variety of other details. Compensating at low gains adds extra components and requires more effort on the part of the design engineer. It is not recommended except for those well versed in RF layout and compensation of high frequency amplifiers. Techniques and tested performance of low gain compensation may be found in application note OA-17 for the CLC422. This is available from Comlinear.

**Printed circuit layout**

As with any high frequency device, a good PCB layout will enhance performance. Ground plane construction and good power supply bypassing close to the package are critical to achieving full performance. The amplifier is sensitive to stray capacitance to ground at the output and inverting input: node connections should be small with minimal coupling to the ground plane.

Parasitic or load capacitance directly on the output (pin 6) will introduce additional phase shift in the loop degrading the loop phase margin and leading to frequency response peaking. A small series resistor before this capacitance, if present, effectively decouples this effect. The graphs on the preceding page, “Settling Time vs. Capacitive Load”, illustrate the required resistor value and resulting performance vs. capacitance.

**Evaluation Board**

Evaluation PC boards (part number 730013 for through-hole and 730027 for SOIC) for the CLC422 are available.
APPLICATIONS:
- instrumentation sense amplifiers
- ultrasound pre-amps
- magnetic tape & disk pre-amps
- photo-diode transimpedance amplifiers
- wide band active filters
- low noise figure RF amplifiers
- professional audio systems
- low-noise loop filters for PLLs

DESCRIPTION
The CLC425 combines a wide bandwidth (1.7GHz GBW) with very low input noise (1.05nV/√Hz, 1.6pA/√Hz) and low dc errors (100μV Vos, 2μV/°C drift) to provide a very precise, wide dynamic-range op amp offering closed-loop gains of ≥10.

Singly suited for very wideband high-gain operation, the CLC425 employs a traditional voltage-feedback topology providing all the benefits of balanced inputs, such as low offsets and drifts, as well as a 96dB open-loop gain, a 100dB CMRR and a 95dB PSRR.

The CLC425 also offers great flexibility with its externally adjustable supply current, allowing designers to easily choose the optimum set of power, bandwidth, noise and distortion performance. Operating from ±5V power supplies, the CLC425 defaults to a 1mA quiescent current, or by adding one external resistor, the supply current can be adjusted to less than 5mA.

The CLC425’s combination of ultra-low noise, wide gain-bandwidth, high slew rate and low dc errors will enable applications in areas such as medical diagnostic ultrasound, magnetic tape & disk storage, communications and opto-electronics to achieve maximum high-frequency signal-to-noise ratios.

The CLC425 is available in the following versions.
- CLC425AJP -40°C to +85°C 8-pin PDIP
- CLC425AJE -40°C to +85°C 8-pin SOIC
- CLC425AIB -40°C to +85°C 8-pin CerDIP
- CLC425A8B -55°C to +125°C 8-pin CerDIP, MIL-STD-883 Level B
- CLC425A8L-2 -55°C to +125°C 20-pin LCC, MIL-STD-883 Level B
- CLC425A8B -55°C to +125°C 8-pin plastic SOIC, MIL-STD-883 Level B

Contact factory for other packages and DESC SMD number.

FEATURES (typical):
- 1.7GHz gain-bandwidth product
- 1.05nV/√Hz input voltage noise
- 1.6pA/√Hz input current noise
- 100μV input offset voltage, 2μV/°C drift
- 350V/μs slew rate
- 15mA to 5mA adjustable supply current
- gain range ±10 to ±1,000V/V
- evaluation board and simulation macromodel

Equivalent Input Voltage Noise

Pinout

Chip Topography

Thickness is 0.014in. Note: Backside connected to Vcc. It is not necessary to electrically connect the backside to the negative power supply. Contact factory for more information.

Introduction

The CLC425 is a very wide gain-bandwidth, ultra-low noise voltage feedback operational amplifier which enables application areas such as medical diagnostic ultrasound, magnetic tape & disk storage and fiber-optics to achieve maximum high-frequency signal-to-noise ratios. The set of characteristic plots located in the “Typical Performance” section illustrates many of the performance trade-offs. The following discussion will enable the proper selection of external components in order to achieve optimum device performance.

Bias Current Cancellation

In order to cancel the bias current errors of the non-inverting configuration, the parallel combination of the gain-setting (Rg) and feedback (Rf) resistors should equal the equivalent source resistance (Rseq) as defined in Figure 1. Combining this constraint with the non-inverting gain equation also seen in Figure 1, allows both Rf and Rg to be determined explicitly from the following equations:

\[ R_f = AV \cdot R_{seq} \]

\[ R_g = R_f \cdot (AV - 1) \]

When driven from a 0Ω source, such as that from the output of an op amp, the non-inverting input of the CLC425 should be isolated with at least a 25Ω series resistor.

As seen in Figure 2, bias current cancellation is accomplished for the inverting configuration by placing a resistor (Rb) on the non-inverting input equal in value to the resistance seen by the inverting input (\( R_{in} = (R_f \cdot R_g) \)). Rb is recommended to be no less than 25Ω for best CLC425 performance. The additional noise contribution of Rb can be minimized through the use of a shunt capacitor.

Total Input Noise vs. Source Resistance

In order to determine maximum signal-to-noise ratios from the CLC425, an understanding of the interaction between the amplifier’s intrinsic noise sources and the noise arising from its external resistors is necessary.

Figure 3 describes the noise model for the non-inverting amplifier configuration showing all noise sources. In addition to the intrinsic input voltage noise (\( e_n \)) and current noise (\( i_n = i_{in+} = i_{in-} \)) sources, there also exists thermal voltage noise (\( e_t = \sqrt{4kT} \)) associated with each of the external resistors. Equation 1 provides the general form for total equivalent input voltage noise density (\( e_{in} \)). Equation 2 is a simplification of Equation 1 that assumes \( R_{in} = R_g = R_{seq} \) for bias current cancellation. Figure 4 illustrates the equivalent noise model using this assumption. Figure 5 is a plot of \( e_{in} \) against equivalent source resistance (\( R_{seq} \)) with all of the contributing voltage noise sources of Equation 2 shown. This plot gives the expected \( e_{in} \) for a given \( R_{seq} \) which assumes \( R_{in} = R_g = R_{seq} \) for bias current cancellation. The total equivalent output voltage noise (\( e_{ov} \)) is \( e_{in} \cdot AV \).
As seen in Figure 5, $e_{in}$ is dominated by the intrinsic voltage noise ($e_n$) of the amplifier for equivalent source resistances below 33.5Ω. Between 33.5Ω and 6.43kΩ, $e_{in}$ is dominated by the thermal noise ($e_n=\sqrt{4kT}\sqrt{R_{eq}}$) of the external resistors. Above 6.43kΩ, $e_{in}$ is dominated by the amplifier’s current noise ($\sqrt{2i_n R_{eq}}$). The point at which the CLC425’s voltage noise and current noise contribute equally occurs for $R_{eq}=464Ω$ (i.e. $e_n/\sqrt{2}$). As an example, configured with a gain of +20V/V giving a -3dB of 90MHz and driven from an $R_{eq}=25Ω$, the CLC425 produces a total equivalent input noise voltage ($e_{in}=\sqrt{1.57*90MHz}$) of 16.5μVrms.

![Figure 5: Voltage Noise Density vs. Source Resistance](image)

If bias current cancellation is not a requirement, then $R1||R\beta$ does not need to equal $R_{eq}$. In this case, according to Equation 1, $R/|R\beta$ should be as low as possible in order to minimize noise. Results similar to Equation 1 are obtained for the inverting configuration of Figure 2 if $R_{eq}$ is replaced by $R\beta$ and $R\alpha$ is replaced by $R\beta+R\alpha$. With these substitutions, Equation 1 will yield an $e_{in}$ referred to the non-inverting input. Referring $e_{in}$ to the inverting input is easily accomplished by multiplying $e_{in}$ by the ratio of non-inverting to inverting gains.

### Noise Figure

Noise Figure (NF) can be defined as the ratio of the total output noise power ($e_{out}$) to that portion of output noise power caused by the source resistance ($e_n+\Delta A$) and is so expressed in Equation 3. This definition assumes an unterminated source and that the parallel combination of $R\alpha$ and $R\beta$ is chosen to equal to $R\alpha$ for bias current cancellation. The curve labeled “Unterminated” in Figure 6 is a plot of NF vs. $R\alpha$ and for a 50Ω source the CLC425’s NF is 5.26dB.

\[
NF = 10\log\left(\frac{e_{out}^2 + 2(i_n R\beta)^2 + 4kT(2R\alpha)}{4kT R\alpha}\right)
\]

*Equation 3: Noise Figure Equation for Unterminated Source*

Adding a matching termination resistor ($R\tau$, Figure 1) to the CLC425’s input will result in a higher measured Noise Figure as seen by the curve labeled “Terminated”. Noise Figure can also be defined as the ratio of the source’s SNR to the amplifier’s SNR. Therefore, even though the thermal noise power contribution of all the external resistors is diminished by $\frac{1}{2}$ (i.e. $R/|R\beta=R\alpha=\frac{1}{2}R\alpha$), the addition of the matching termination resistor as a part of the amplifier also cuts the input signal amplitude by $\frac{1}{2}$ such that the amplifier’s SNR is reduced and the resulting Noise Figure is higher as shown in the plot. From the curve labeled “Terminated”, the CLC425 configured with a 50Ω matching termination resistor ($R\tau$) driven from the same 50Ω source used above, yields a NF of 9.72dB. As seen from the two curves, the difference is negligible with very high source resistances where the current noise of the amplifier becomes the dominant factor. For more information regarding Noise Figure, see OA-11.

### Supply Current Adjustment

The CLC425’s supply current can be externally adjusted downward from its nominal value by adding an optional resistor ($R\beta$) between pin 8 and the negative supply as shown in Figure 7. Several of the plots found within the plot pages demonstrate the CLC425’s behavior at different supply currents. The plot labeled “I\_cc vs. R\beta” provides the means for selecting $R\beta$ and shows the result of standard IC process variation which is bounded by the 25°C curve.

![Figure 7: External Supply Current Adjustment](image)

### Non-Inverting Gains Less Than 10V/V

Using the CLC425 at lower non-inverting gains requires external compensation such as the shunt compensation as shown in Figure 8. The quiescent supply current must also be reduced to 5mA with $R\beta$ for stability. The compensation capacitors are chosen to reduce frequency response peaking to less than 1dB. The plot in the “Typical Performance” section labeled “Differential Gain and Phase” shows the video performance of the CLC425 with this compensation circuitry.
Inverting Gains Less Than 10V/V
The lag compensation of Figure 9 will achieve stability for lower gains. Placing the network between the two input terminals does not affect the closed-loop nor noise gain, but is best used for the inverting configuration because of its affect on the non-inverting input impedance.

Single-Supply Operation
The CLC425 can be operated with single power supply as shown in Figure 10. Both the input and output are capacitively coupled to set the dc operating point.

Low Noise Transimpedance Amplifier
The circuit of Figure 11 implements a low-noise transimpedance amplifier commonly used with photodiodes. The transimpedance gain is set by $R_t$. The simulated frequency response is shown in Figure 12 and shows the influence $C_t$ has over gain flatness. Equation 4 provides the total input current noise density ($i_{in}$) equation for the basic transimpedance configuration and is plotted against feedback resistance ($R_f$) showing all contributing noise sources in Figure 13. This plot indicates the expected total equivalent input current noise density ($i_{ei}$) for a given feedback resistance ($R_f$). The total equivalent output voltage noise density ($e_{vo}$) is $i_{ei}R_f$.

Very Low Noise Figure Amplifier
The circuit of Figure 14 implements a very low Noise Figure amplifier using a step-up transformer combined with a CLC425 and a CLC404. The circuit is configured with a gain of 35.6dB. The circuit achieves measured Noise Figures of less than 2.5dB in the 1-40MHz region. 3rd order intercepts exceed +30dBm for frequencies less than 40MHz and gain flatness of 0.5dB is measured in the 1-50MHz pass bands. Application Note OA-14 provides greater detail on these low Noise Figure techniques.
Low Noise Integrator
The CLC425 implements a deBoo integrator shown in Figure 15. Integration linearity is maintained through positive feedback. The CLC425's low input offset voltage and matched inputs allowing bias current cancellation provide for very precise integration. Stability is maintained through the constraint on the circuit elements.

\[
V_o \equiv V_{in} \frac{K_o}{sR_cC} ; \quad K_o = 1 + \frac{R_f}{R_g}
\]

\[
\frac{R_o}{R_1} \approx \frac{R_f}{R_g} , \quad R >> R_o
\]

Figure 15: Low Noise Integrator

High-Gain Sallen-Key Active Filters
The CLC425 is well suited for high-gain Sallen-Key type of active filters. Figure 16 shows the 2\textsuperscript{nd} order Sallen-Key low pass filter topology. Using component predistortion methods as discussed in OA-21 enables the proper selection of components for these high-frequency filters.

Figure 16: Sallen-Key Active Filter Topology

Low Noise Magnetic Media Equalizer
The CLC425 implements a high-performance low-noise equalizer for such applications as magnetic tape channels as shown in Figure 17. The circuit combines an integrator with a bandpass filter to produce the low-noise equalization. The circuit's simulated frequency response is illustrated in Figure 18.

Figure 17: Low Noise Magnetic Media Equalizer

Low-Noise Phase-Locked Loop Filter
The CLC425 is extremely useful as a Phase-Locked Loop filter in such applications as frequency synthesizers and data synchronizers. The circuit of Figure 19 implements one possible PLL filter with the CLC425.

Figure 18: Equalizer Frequency Response

Decreasing the Input Noise Voltage
The input noise voltage of the CLC425 can be reduced from its already low 1.05nV/\sqrt{Hz} by slightly increasing the supply current. Using a 50kΩ resistor to ground on pin 8, as shown in the circuit of Figure 14, will increase the quiescent current to ~17mA and reduce the input noise voltage to < 0.95nV/\sqrt{Hz}.

Printed Circuit Board Layout
Generally, a good high-frequency layout will keep power supply and ground traces away from the inverting input and output pins. Parasitic capacitances on these nodes to ground will cause frequency response peaking and possible circuit oscillation, see OA-15 for more information. Comlinear suggests the 730013 Evaluation Board both as a guide for high-frequency layout and as an aid in device testing and characterization.
APPLICATIONS:
• video distribution
• multiple-line driver
• analog bus driver
• video signal multiplexing
• DAC output buffer
• CCD amplifier

DESCRIPTION:
The CLC 430 is a high-speed, monolithic operational amplifier employing Comlinear’s proprietary current feedback architecture. Equipped with a very fast disable/enable feature, the CLC430 is designed specifically for video switching and distribution systems. The CLC430’s high-speed operation includes a 55MHz small-signal bandwidth (4Vpp) and a 2000V/μs slew rate while requiring only 11mA quiescent current. Since the CLC430 is designed to operate over a wide range of supply voltages, there is little degradation in performance between ±5V and ±15V operation.

The CLC430 is designed to drive video speed signals through multiple 75Ω or 50Ω channels while maintaining excellent differential gain and phase performance. The disable/enable feature allows the CLC430 to be used in video switching and multiplexing applications with its quick turn-off (100ns) and turn-on (200ns). Switched into disable mode, the CLC430 provides a high impedance output while drawing only 1.5mA supply current. Multiplexing video signals onto an analog bus can easily be achieved by combining parallel CLC430s to form a common output. And since “break before make” is guaranteed, the disable pins of the paralleled combination can be driven with the same signal source.

Applications with large DC components, such as CCD amplifiers will enjoy the CLC430’s high common mode input range and wide signal swing.

The CLC430 is available in several versions to meet a variety of requirements.

CLC430AJP ~ 40°C to +85°C 8-pin plastic DIP
CLC430AJE ~ 40°C to +85°C 8-pin plastic SOIC
CLC430AIB ~ 40°C to +85°C 8-pin hermetic CERDIP
CLC430AIB ~ 55°C to +125°C 8-pin hermetic CERDIP
MIL-STD-883, Level B
CLC430ALC ~ 55°C to +125°C dice
CLC430AMC ~ 55°C to +125°C dice qualified to Method 5008, MIL- STD-883, Level B

Enable/Disable Operation
The CLC430 has a disable feature which allows several CLC430 outputs to be multiplexed on an analog output bus. When disabled, the CLC430 output and inverting input become a high impedance, and the amplifier quiescent power is reduced. The device is guaranteed to be disabled when the DIS line, pin 8, is grounded. An internal 10kΩ pull-up resistor ensures the amplifier is enabled when pin 8 is left floating or connected to the positive supply. Current, not voltage, determines the enabled state of the CLC430. Logic swings of 0V to +V_{CC} are required by the CLC430 disable pin. Open-collector TTL, or CMOS supplied from the same positive supply will effectively drive the disable feature of the CLC430.

Break-before-make operation is desirable to prevent large transient currents between amplifier outputs connected to the same output bus. The turn-on vs. turn-off time of the CLC430 guarantees two amplifiers will not be enabled simultaneously when driven from the same decoder circuit. Refer to Figure 3A on the CLC410 datasheet for a typical multiplexing circuit.

Feedback Resistor
The loop gain and frequency response for a current feedback amplifier is determined predominantly by the feedback resistor, R_{T}. The datasheet electrical characteristics and typical performance plots, unless stated otherwise, specify a 750Ω R_{T}, a gain of +2, and ±15V supplies. Frequency response at different gains and supply voltages can be optimized by using a different value for R_{T}. Generally, lowering R_{T} will peak the frequency response and extend the bandwidth, while increasing its value will roll off the response. For unity-gain voltage follower circuits a non-zero R_{T} must be used with current feedback amplifiers such as the CLC430.

Application note OA-13 gives a detailed explanation of choosing R_{T}. The equations in the application note are to be considered as a starting point for the selection of R_{T}, and do not include the effects of parasitic capacitance at the inverting input, output, nor across the feedback resistor. The value for the inverting input impedance (R_{I} in OA-13) for the CLC430 is 60Ω when supplied from ±15V, a little higher at lower supply voltages. The following plot entitled “Recommended R_{T} vs. Gain” is to be used to choose a value of R_{T} which will optimize the frequency response of the CLC430 over its entire recommended gain range. For ±5V operation a 675Ω feedback resistor at a gain of ±2 gives best response.

Differential Gain and Phase
The differential gain and phase of the CLC430 driving one video load (R_{L}=150Ω) is specified and guaranteed on the Electrical Characteristics table. A Typical Performance plot shows differential gain and phase with the part driving from one to four video loads. The technique used for measuring differential gain and phase is described in detail in application note OA-08.

Printed Circuit Layout
As with any high-speed amplifier, careful attention to circuit board layout is necessary for best performance. Of particular importance is the control of parasitic capacitance at the output and inverting input pins. Protoboards, sockets, and wirewrap construction must not be used due to the excessive parasitic capacitance and inductance resulting from such circuit construction techniques. A good low-impedance ground plane, and high-frequency power supply bypassing immediately adjacent to the device pins are critical to realizing full performance. The key to successful circuit operation is to be aware of frequencies at which the amplifier has power gain, not simply the frequency of the input signal. A discussion circuit design and construction guidelines applicable to the CLC430 can be found in application note OA-1 5.

Evaluation Board
Evaluation boards (part number 730013 for through-hole and 730027 for SOIC) for the CLC430 are available. This board can be used for fast, trouble-free evaluation and characterization of the CLC430, and as a template for engineers designing their own printed circuit boards. Applications schematics for this board can be found in the product accessories section of the Comlinear databook.
APPLICATIONS:
- residue amplifier in high-accuracy, subranging A/D systems
- high-speed communications
- output clamping applications
- pulse amplitude modulation systems

DESCRIPTION:
The CLC501 is a high-speed current-feedback op amp with the unique feature of output voltage clamping. This feature allows both the maximum positive \( (V_{\text{high}}) \) and negative \( (V_{\text{low}}) \) output voltage levels to be established. This is useful in a number of applications in which "downstream" circuitry must be protected from overdriving input signals. Not only can this prevent damage to downstream circuitry, but can also reduce time delays since saturation is avoided. The CLC501’s very fast 1 ns overload/clamping recovery time is useful in applications in which information-containing signals follow overdriving signals.

Engineers designing high-resolution, subranging A/D systems have long sought an amplifier capable of meeting the demanding requirements of the residue amplifier function. Amplifiers providing the residue function must not only settle quickly, but recover from overdrive quickly, protect the second stage A/D, and provide high fidelity at relatively high gain settings. The CLC501, which excels in these areas, is the ideal design solution in this onerous application. To further support this application, the CLC501 is both characterized and tested at a gain setting of +32—the most common gain setting for residue amplifier applications.

The CLC501’s other features provide a quick, high-performance design solution. Since the CLC501’s current feedback design requires no external compensation, designers need not spend their time designing compensation networks. The small 8-pin package and low, 180mW power consumption make the CLC501 ideal in numerous applications having small power and size budgets.

The CLC501 is available in several versions to meet a variety of requirements. A three-letter suffix determines the version:

- CLC501AJP - 40 °C to + 85 °C
- CLC501AJE - 40 °C to + 85 °C
- CLC501AID - 40 °C to + 85 °C
- CLC501A8D - 55 °C to + 125 °C

Contact factory for other packages. DESC SMD number is 5962-89974.

FEATURES (typical):
- output clamping \( (V_{\text{high}} \) and \( V_{\text{low}}) \)
- 1ns recovery from clamping/overdrive
- 0.05% settling in 12ns
- characterized and guaranteed at \( A_v = + 32 \)
- low power, 180mW

Comlinear reserves the right to change specifications without notice.
Clamp Operation

The maximum positive or negative excursion of the output voltage is determined by voltages applied to the clamping pins, \( V_H \) and \( V_L \). \( V_H \) determines the positive clamping level; \( V_L \) determines the negative level. For example, if \( V_H \) is set at \(+2V\) and \( V_L \) is set at \(-0.5V\) the output voltage is restricted within this \(-0.5V\) to \(+2V\) range. When the output voltage tries to exceed this level, the amplifier goes into "clamp mode" and the output voltage limits at the clamp voltage.

Clamp Accuracy and Amplifier Linearity

Ideally, the clamped output voltage and the clamp voltage should be identical. In practice, however, there are two sources of clamp inaccuracy: the inherent clamp accuracy (which is shown in the specification page) and resistor divider action of open-loop output resistance of \( 10\Omega \) and the load resistor. Or, in equation form,

\[
V_{out, clamp} = \left( V_H \text{ or } L \pm 200mV \right) \frac{R_L}{R_L + 10\Omega}
\]

When setting the clamp voltages, the designer should also recognize that within about \( 200mV \) of the clamp voltage, amplifier linearity begins to deteriorate. (See plot on previous page.)

Biasing \( V_H \) and \( V_L \)

Each of the clamping pins is buffered internally so simple resistive voltage divider circuits work well in providing the clamp voltages (see Figure 3). The \( 100\Omega \) isolating resistor ensures stability when the clamp pin is connected to \( V_{CC} \) or when the clamp pin is driven by an external signal source; in other situations, such as the one described in Figure 3, the isolating resistor is not necessary.

\( V_H \) should be biased more positively than \( V_L \). \( V_H \) may be biased below \( 0V \); however, with this biasing, the output voltage will actually clamp at \( 0V \) unless a simple pull down circuit is added to the op amp output. (When clamped against \( V_H \) the output cannot sink current.) An analogous situation and design solution exists for \( V_L \) when it is biased above \( 0V \), but in this case, a pull up circuit is used to source current when the amplifier is clamped against \( V_L \).

The clamps, which have a bandwidth of about \( 50MHz \), may be driven by a high-frequency signal source. This allows the clamping level to be modulated, which is useful in many applications such as pulse amplitude modulation. The source resistance of the signal source should be less than \( 500\Omega \) to ensure stability.

Clamp-Mode Dynamics

As can be seen in the clamped pulse response plot on the previous page, clamping is virtually instantaneous. Note, however, that there can be a small amount of overshoot, as indicated on the specification page. The output voltage stays at the clamp voltage level as long as the product of the input voltage and the gain setting exceeds the clamp voltage. When the input voltage decreases, it will eventually reach a point where it is no longer trying to drive the output voltage above the clamp voltage. When this occurs, there is typically a 1ns "overload recovery from clamp," which is the time it takes for the op amp to resume linear operation. The normal op amp parameters, such as the rise time, apply when the op amp is in linear operation.

When the op amp is in clamp mode for more than about 100ns, a small thermal tail can be detected in the settling performance. This tail, which has a maximum value of \( 200\mu V \) referred to the input, is proportional to the amount of time spent in clamp mode. In most applications, this will have only a minor effect. For example, in a system with a \( 100ns \) overdrive occurring with a duty cycle of 10%, the input-referred tail is \( 20\mu V \) which is only \( 0.001\% \) of a \( 2V \) signal.

DC Accuracy and Noise

Since the two inputs for the CLC501 are quite dissimilar, the noise and offset error performance differs somewhat from that of a standard differential input amplifier. Specifically, the inverting input current noise is much larger than the non-inverting current noise. Also, the two input bias currents are physically unrelated rendering bias current cancellation through matching of the inverting and non-inverting pin resistors ineffective.

In Equation 3, the output offset is the algebraic sum of the equivalent input voltage and current sources that influence DC operation. Output noise is determined similarly except that a root-sum-of-squares replaces the algebraic sum. \( R_s \) is the non-inverting pin resistance.

\[
\text{Output Offset } V_o = \pm \text{IBN} \times R_s \left( 1 + R_v/R_a \right) \pm \text{IO} \times (1 + R_v/R_a) \pm \text{IBI} \times R_i
\]

PSRR and CMRR

The PSRR and CMRR performance plots on the previous page show performance for a circuit set at a gain of \( +32 \) and a source resistance of \( 0\Omega \). In current feedback op amps, common mode and power supply variations manifest themselves in changes in the op amp's bias currents (IBN for the inverting input and IBN for the non-inverting input) and in the offset voltage (VIO). At DC, these values are:

\[
\begin{align*}
\text{CMRR: } & \Delta V_{IO} = 130\mu V/V \quad \text{PSRR: } \Delta V_{IO} = 180\mu V/V \\
\Delta V_{CM} & = 6\mu V/V \quad \Delta V_{IO} = 3\mu V/V \\
\Delta I_{IBN} & = 2\mu A/V \quad \Delta I_{IBN} = 3\mu A/V \\
\Delta I_{IBI} & = 2\mu A/V \quad \Delta I_{IBI} = 3\mu A/V
\end{align*}
\]

The total effect, as referenced to the input, is given by the following:

\[
\begin{align*}
\text{PSRR: } & = -20 \log \left[ \Delta V_{IO} + \Delta I_{IBN} + \Delta I_{IBI} \right] \\
\text{CMRR: } & = -20 \log \left[ \Delta V_{CM} + \Delta I_{IBN} + \Delta I_{IBI} \right]
\end{align*}
\]

Where \( R_i \) is the equivalent resistance seen by the non-inverting input and \( R_{eq} \) is the equivalent resistance of \( R_s \) in parallel with \( R_i \).

Printed Circuit Layout

As with any high frequency device, a good PCB layout will enhance performance. Ground plane construction and good power supply bypassing close to the package are critical to achieving full performance. In the non-inverting configuration, the amplifier is sensitive to stray capacitance to ground at the inverting input. Hence, the inverting node connections should be small with minimal coupling to the ground plane. Shunt capacitance across the feedback resistor should not be used to compensate for this effect.

Evaluation PC boards (part number 730013 for through-hole and 730027 for SOIC) for the CLC501 are available.
APPLICATONS:
- output clamping applications
- high-accuracy A/D systems (12-14 bits)
- high-accuracy D/A converters
- pulse amplitude modulation systems

DESCRIPTION:
The CLC502 is an operational amplifier designed for low-gain applications requiring output voltage clamping. This feature allows the designer to set maximum positive and negative output voltage levels for the amplifier – thus allowing the CLC502 to protect downstream circuitry, such as delicate converter systems, from destructive transients or signals which would otherwise cause saturation. The overload recovery time of only 8ns permits systems to resume operation quickly after overdrive.

High-accuracy systems will also benefit from the CLC502’s fast, accurate settling. Settling to 0.0025% in 25ns (32ns guaranteed over temperature), the CLC502 is ideal as the input amplifier in high-accuracy (12 bits and above) A/D systems. Unlike most other high-speed op amps, the CLC502 is free of settling tails. And, as the settling plots show, settling to 0.01% accuracy is an even faster 18ns typical.

The CLC502 is also useful in other applications which require low-gain amplification (±1 to ±8) and the clamping or overload recovery features. For example, even low-resolution imaging circuits, which often have to cope with overloading signal levels, can benefit from clamping and overload recovery.

The CLC502 is available in several versions to meet a variety of requirements. A three-letter suffix determines the version:

- CLC502AJP: -40°C to +85°C 8-pin plastic DIP
- CLC502AJE: -40°C to +85°C 8-pin plastic SOIC
- CLC502AID: -40°C to +85°C 8-pin hermetic side-brazed ceramic DIP
- CLC502A8D: -55°C to +125°C 8-pin hermetic side-brazed ceramic DIP, MIL-STD-883, Level B

Sample tested at +25°C, −55°C, +125°C.

Sample tested at +25°C to −55°C, +125°C.

Differential gain and phase measured at $A_{in}$ = +2V, $R_{in}$ = 250Ω.

Gain flatness tests begin at 0.1 MHz.

$R_{in}$ = 150Ω, $V_{in}$ equivalent video signal, 0-100 IRE, 40 IRE, 0 IRE = 0 volts, at 75Ω load and 3.58 MHz.

Comlinear reserves the right to change specifications without notice.
Clamp Operation

The maximum positive or negative excursion of the output voltage is determined by voltages applied to the clamping pins, \( V_H \) and \( V_L \). \( V_H \) determines the positive clamping level; \( V_L \) determines the negative level. For example, if \( V_H \) is set at +2V and \( V_L \) is set at -0.5V the output voltage is restricted within this -0.5V to +2V range. When the output voltage tries to exceed this level, the amplifier goes into “clamp mode” and the output voltage limits at the clamp voltage.

Clamp Accuracy and Amplifier Linearity

Ideally, the clamped output voltage and the clamp voltage should be identical. In practice, however, there are two sources of clamp inaccuracy: the inherent clamp accuracy (which is shown in the specification page) and resistor divider action of open-loop output resistance of 10Ω and the load resistor. Or, in equation form,

\[
V_{out, clamp} = \frac{(V_H - L \pm 300mV) R_L}{R_L + 10Ω}.
\]

When setting the clamp voltages, the designer should also recognize that within about 200mV of the clamp voltage, amplifier linearity begins to deteriorate. (See plot on previous page.)

Biasing \( V_H \) and \( V_L \)

Each of the clamping pins is buffered internally so simple resistive voltage divider circuits work well in providing the clamp voltages. \( V_H \) and \( V_L \) can be set by choosing the divider resistors using:

\[
V_H = (5V) \left( \frac{R_2}{R_1 + R_2} \right) \quad V_L = (-5V) \left( \frac{R_3}{R_3 + R_4} \right).
\]

As a general guideline, let \( R_1 + R_2 = R_3 + R_4 = 5kΩ \).

\( V_H \) should be biased more positively than \( V_L \); \( V_L \) may be biased below 0V; however, with this biasing, the output voltage will actually clamp at 0V unless a simple pull down circuit is added to the op amp output (when clamped against \( V_L \), the output cannot sink current). An analogous situation and design solution exists for \( V_L \) when it is biased above 0V, but in this case, a pull up circuit is used to source current when the amplifier is clamped against \( V_L \).

The clamp voltage range rating is that for normal operation. Problems in overdriven linearity may occur if the clamps are set outside this range so this is not suggested under any conditions. If the clamping capability is not required, the CLC402 (low-gain op amp with fast 14-bit settling) may be the more appropriate part.

The clamps, which have a bandwidth of about 50MHz, may be driven by a high-frequency signal source. This allows the clamping level to be modulated, which is useful in many applications such as pulse amplitude modulation. The source resistance of the signal source should be less than 50Ω to ensure stability.

Clamp-Mode Dynamics

As can be seen in the clamped pulse response plot on the previous page, clamping is virtually instantaneous. Note, however, that there can be a small amount of overshoot, as indicated on the specification page. The output voltage stays at the clamp voltage level as long as the product of the input voltage and the gain setting exceeds the clamp voltage. When the input voltage decreases, it will eventually reach a point where it is no longer trying to drive the output voltage above the clamp voltage. When this occurs, there is typically a 5-10ns “overload recovery from clamp,” which is the time it takes for the op amp to resume linear operation. The normal op amp parameters, such as the rise time, apply when the op amp is in linear operation.

Optimizing Settling Time Performance

To obtain the best possible settling time performance for the CLC502, some additional design criteria must be considered, particularly when driving loads of less than 500Ω. When driving a 100Ω load, a step of a few volts on the output will create a large step of current in the power supplies. In some cases, this step will cause a small ringing on the power supply due to the bypass capacitor (1 μF) oscillating with the inductance in the power supply trace. The critical trace is the power supply trace between the two capacitors (a trace inductance of 20nH will be enough to degrade settling time performance). The frequency of the ring can be determined by

\[
f = \frac{1}{2\pi \sqrt{C \cdot L}}
\]

and any reduction in this frequency will improve performance due to better power supply rejection at lower frequencies. To obtain the best performance, a small resistor, \( R_o \), may be added in the trace to dampen the circuit (See Figure 3). An \( R_o \) of 5-10Ω will result in excellent settling performance and will have only minor impact on other performance characteristics. No provision for \( R_o \) has been made on the evaluation board available from Comlinear as part #730013. It can, however, be easily added by cutting a trace and adding a 5-10Ω resistor, as shown in Figure 3, for both supplies.

DC Accuracy and Noise

Since the two inputs for the CLC502 are quite dissimilar, the noise and offset error performance differs somewhat from that of a standard differential input amplifier. The two input bias currents are physically unrelated rendering bias current cancellation through matching of the inverting and non-inverting source resistance ineffective.

In equation 3, the output offset is the algebraic sum of the equivalent input voltage and current sources that influence DC operation. Output noise is determined similarly except that a root-sum-of-squares replaces the algebraic sum. \( R_o \) is the non-inverting pin source resistance.

\[
\text{Output Offset } V_o = \pm \text{IBN} \times R_o (1 + R_1/R_2) \pm \text{VIO} \times (1 + R_1/R_2) \pm \text{IBL} \times R_1
\]

Eq. (3)

Printed Circuit Layout

As with any high frequency device, a good PCB layout will enhance performance. Ground plane construction and good power supply bypassing close to the package are critical to achieving full performance. In the non-inverting configuration, the amplifier is sensitive to stray capacitance to ground at the inverting input. Hence, the inverting node connections should be small with minimal coupling to the ground plane. Shunt capacitance across the feedback resistor should not be used to compensate for this effect.

The device is also very sensitive to parasitic capacitance on the output pin. The plots include a suggested series \( R_o \) to de-couple this effect. Evaluation boards (part number 730013 for through-hole and 730027 for SOIC) for the CLC502 are available.
APPLICATIONS:
- low-power/battery applications
- remote site instrumentation
- mobile communications gear
- video switching matrix
- phased-array radar

DESCRIPTION:
The CLC505 is a monolithic, high-speed op amp with a unique combination of high performance, low power consumption, and flexibility of operation. With a 10 to 1 range of supply current programmability (not preset currents, but rather a continuous range "programmed" with a single external resistor, \( R_p \)), this amplifier can be used in a wide variety of high-performance applications. Performance (typical) at any supply current is exceptional:

<table>
<thead>
<tr>
<th>parameter</th>
<th>Supply Current (I_{cc})</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>1mA</td>
</tr>
<tr>
<td>-3dB bandwidth</td>
<td>50</td>
</tr>
<tr>
<td>settling time</td>
<td>35</td>
</tr>
<tr>
<td>slew rate</td>
<td>800</td>
</tr>
<tr>
<td>output current</td>
<td>7</td>
</tr>
</tbody>
</table>

Even at 10mW power consumption, the CLC505 provides performance far beyond other monolithic op amps, many of which consume nearly 100 times as much power.

The CLC505’s combination of high performance, low power consumption, and large signal performance makes the CLC505 ideal for many demanding applications in which power consumption must be minimized. Examples include a variety of remote site equipment such as battery-powered test instrumentation and communications gear. Power is also critical in applications requiring many channels, such as video switching matrices, ATE, and phased-array radar systems.

The CLC505 has been designed for ease of use and has been specified for design confidence and predictability. The following pages include three complete data sheets, one for operation at 1mA supply current, one at 3.4mA, and one at 9mA. Specifications are guaranteed and tested at all three supply currents. The CLC505 is also available in several versions specified by the three-letter suffix:

- CLC505AJP -40°C to +85°C 8-pin plastic DIP
- CLC505AJE -40°C to +85°C 8-pin plastic SOIC
- CLC505AID -55°C to +125°C 8-pin side-brazed ceramic DIP, MIL-STD-883, Level B
- CLC505ALC -55°C to +125°C dice
- CLC505AMC -55°C to +125°C dice qualified to Method 5008, MIL-STD-883, Level B

Contact factory for other packages. DESC SMD number, 5962-90993.

FEATURES (typical):
- 10mW power consumption with 50MHz BW
- single-resistor programming of supply current
- 3.4mA \( I_{cc} \) provides 100MHz bandwidth and 14ns settling (0.05%)
- fast disable capability
- 0.04% differential gain at \( I_{cc} = 3.4mA \)
- 0.06° differential phase at \( I_{cc} = 3.4mA \)
Electrical Characteristics \( (A_A = 6, V_{CC} = 5.0\text{V}, R_P = 33k\Omega, R_I = 250\Omega) \)

Description
The CLC505 is a programmable-supply current, current-feedback operational amplifier. Supply current and consequently dynamic performance can be easily adjusted by selecting the value of a single external resistor (R_p). This capability is reflected in the datasheet by three complete sets of specifications, each at a different value of supply current.

Selecting an Operating Point
The operating point is determined by the supply current, which in turn is determined by current (I_p) flowing out of pin 8. As the supply current is reduced the following effects will be observed:

<table>
<thead>
<tr>
<th>Specification</th>
<th>Effect as I_cc decreases</th>
</tr>
</thead>
<tbody>
<tr>
<td>bandwidth</td>
<td>decreases</td>
</tr>
<tr>
<td>rise time</td>
<td>increases</td>
</tr>
<tr>
<td>output drive</td>
<td>decreases</td>
</tr>
<tr>
<td>input bias current</td>
<td>increases</td>
</tr>
<tr>
<td>input impedance</td>
<td>(see source impedance discussion)</td>
</tr>
</tbody>
</table>

Both the specification pages and the plot pages illustrate these effects to help make the supply current vs. performance tradeoff. Performance is specified and tested at I_cc = 1mA, 3.4mA, and 9mA as indicated in the data sheet. (Note test conditions and especially the load resistance are different for the three supply current settings.) The performance plots show typical performance for all three supply current levels (again, with different load resistors for the various supply currents). Finally, the last set of plots show graphically the relationship between the supply current (I_cc) and various performance parameters, as well as I_cc vs. the programming current, I_p.

When making the supply current vs. performance tradeoff, it is first a good idea to see if one of the standard operating points (I_cc = 9mA, 3.4mA, or 1mA) fits your application. If it does, performance guaranteed on the specification pages will apply directly to your application. In addition, the value of R_p may be obtained directly from the specification page.

The following discussion will assist in selecting I_cc for applications that cannot operate at one of the specified supply current settings.

The typical performance plots should be used to select a value of I_cc suitable to your application's TYPICAL requirement for critical specifications. Then, use the performance plots and the max/min limits on the specification pages to interpolate between values of I_cc to estimate max/min values in your application.

From the selected value of I_cc, the "programming current" (I_p) may be easily calculated:

\[ I_p = \frac{I_{cc}}{39} \]

The plot of I_cc vs I_p in the plot pages shows this relationship graphically. Knowing I_p leads to a direct calculation of R_p:

\[ R_p = \frac{[+V_{cc}-1.6V-8.4]}{I_p} \]

V_n is the voltage externally applied to R_p. (Throughout the data sheet and in most applications, V_n is -Vcc or more specifically, -5V.) The term (+V_cc-1.6V) is the voltage at pin 8.

Since the op amp side of R_p is very nearly at a fixed voltage (V_cc=-1.6V), I_p is a function of V_n and R_p. Therefore does not have to be connected to -Vcc as long as R_p is chosen accordingly. This is beneficial in applications where non-standard supply voltages are used or when there is a need to power down the op amp via digital logic control.

First, an operating point needs to be established as discussed above. From this, I_p is obtained. I_p, in concert with the available V_n, determines R_p.

Example
An application requires that V_cc = + -3V and performance in the 1mA operating point range. The required I_p can therefore be determined as discussed above.

\[ I_p = 26\mu A \]

R_p is connected from pin 8 to V_cc and V_cc = + -3V. Now calculate R_p under new conditions:

\[ R_p = \frac{[+3V-1.6V-3V]}{26\mu A} \]

The CLC505 will have performance similar to R_p = 300kΩ shown on the datasheet, but with 40% less power dissipation due to the reduced supply voltages. (The op-amp will also have a more restricted common-mode range and output swing.) This calculation is approximate and a prudent design would include substantial performance margin for max/min limits. Comlinear application engineers are available for assistance.

Dynamic Shutdown Capability
The CLC505 may be powered on and off very quickly by controlling the voltage applied to R_p. If R_p is connected between pin 8 and the output of a CMOS gate powered from + /-5V supplies, the gate can be used to turn the amplifier on and off. This is shown in figure 3 below:

Figure 3: dynamic control of power consumption
When the gate output is switched from high to low, the CLC505 will turn on. In the off state, the supply current typically reduces to 0.2mA or less. The speed with which the CLC505 turns on or off is limited by the capacitance at pin 8. To improve switching time, a speed up capacitor from the gate output to pin 8 is recommended. The value of this capacitor will depend on the total capacitance connected to pin 8 and is best established experimentally. Turn-on and turn-off times of 100ns to 200ns are achievable with ordinary CMOS gates.

Example:

An open collector logic device is used to dynamically control the power dissipation of the circuit. Here, the desired connection for $R_p$ is from pin 8 to the open collector logic device.

![Open collector TTL gate](image)

Figure 4: controlling power on state with TTL logic

When the logic gate goes low, the CLC505 is turned on. Performance desired is that given for $I_{cc}=3.4$mA under standard conditions. From the $I_{cc}V_{pp}$ plot, $|I_p|=84\mu$A. Then calculating $R_p$:

$$R_p = \frac{[(+V_{cc}-1.6V)-(V_n)]}{I_p}$$

$$R_p = \frac{[(+5V-1.6V)-(0)]}{84\mu}$A$$

$$R_p = 40k\Omega$$

NOTE: The rapid turn on and off ability of the CLC505 is not recommended for signal isolation applications (such as multiplexing). While the power dissipation of the amplifier drops in the off state, the amplifier may still have some gain at low frequencies.

Slew Rate

Slew rate limiting is a nonlinear response which occurs in amplifiers when the output voltage swing approaches hard, abrupt limits in the speed at which it can change. In most applications, this results in an easily identifiable "slew rate" as well as a dramatic increase in distortion for large signal levels. The CLC505 has been designed to provide enough slew rate to avoid slew rate limiting in most circuit configurations. The large signal (5Vpp) bandwidth of 80MHz at $I_{cc}=3.4$mA, therefore, is only slightly less than the 100MHz small signal bandwidth. The result is a low-distortion, linear system for both small signals and large signals.

The CLC505 reaches slew rate limits only for low non-inverting gains. In other words, slew rate limiting is constrained by common mode voltage swings at the input. (This is different from traditional slew rate constraints.) The large-signal frequency response plot at a gain of +2 shows a break in the response, which shows that a slew rate limit has been reached. Note also that the frequency response plots at a gain of +21 show that the large signal and small signal responses are nearly identical.

Differential Gain and Phase

Differential gain and phase are measurements useful primarily in composite video channels. They are measured by monitoring the gain and phase changes of a high frequency carrier (3.58MHz typically) as the output of the amplifier is swept over a range of DC voltages.

Specifications for the CLC505 include differential gain and phase. The test signals used are based on a 1Vpp video level. Test conditions used are the following:

- DC sweep range: 0 to 100 IRE units (black to white)
- Carrier: 3.58MHz at 40 IRE units peak to peak

The amplifier conditions are significantly different for the three values of supply current specified. At $I_{cc}=9$mA, the amplifier is specified for a gain of +2 and 150Ω load (for a backmatched 75Ω system). IRE amplitudes at $I_{cc}=9$mA, are referred to the 75Ω load resistor.

At $I_{cc}=1$mA and $I_{cc}=3.4$mA, the CLC505 is less capable of driving a 150Ω load due to output current limitations. For this reason lighter loads are used and a termination resistor is omitted. The gain and load resistance for $I_{cc}=3.4$mA are $A_v=+6$ and $R_L=5000$. The gain and load resistance for $I_{cc}=1$mA are $A_v=+6$ and $R_L=1K\Omega$.

Source Impedance

For best results, source impedance in the non-inverting circuit configuration (see Figure 1) should be kept below 5kΩ. Above 5kΩ it is possible for oscillation to occur, depending on other circuit parasitics. For high signal source impedances, a resistor with a value of less than 5kΩ may be used to terminate the non-inverting input to ground.

Feedback Resistor

In current-feedback op amps, the value of the feedback resistor plays a major role in determining amplifier dynamics. It is important to select the correct value resistor. The CLC505 provides optimum performance with a 1kΩ feedback resistor. Furthermore, the specifications shown on the previous pages are valid only when a 1kΩ feedback resistor is used. Selection of an incorrect value can lead to severe rolloff in frequency response (if the resistor value is too large) or peaking or oscillation (if the value is too low). See Comlinear application notes AN and AN 300-1 for a complete discussion of current feedback.

Printed Circuit Layout

As with any high frequency device, a good PCB layout will enhance performance. Ground plane construction and good power supply bypassing close to the package are critical to achieving full performance. In the non-inverting configuration, the amplifier is sensitive to stray capacitance to ground at the inverting input. Hence, the inverting node connections should be small with minimal coupling to the ground plane. Shunt capacitance across the feedback resistor should not be used to compensate for this effect.

Precision buffered resistors (PRPB351 series from Precision Resistive Products) with low parasitic reactances were used to develop the data sheet specifications. Precision carbon composition resistors will also yield excellent results. Standard spirally-trimmed RN55D metal film resistors will work with a slight decrease in bandwidth due to their reactive nature at high frequencies.

Evaluation PC boards (part number 730013 for through-hole and 730027 for SOIC) for the CLC505 are available.

APPLICATIONS:
• output amplification
• arbitrary waveform generation
• ATE systems
• cable/line driving
• function generators
• SAW drivers
• flash A/D driving and testing

DESCRIPTION:
The CLC560 is a wideband dc coupled, amplifier that combines high output drive and low distortion. At an output of +24dBm (10Vpp into 50Ω), the -3dB bandwidth is 120MHz. As illustrated in the table below, distortion performance remains excellent even when amplifying high-frequency signals to high output power levels.

With the output current internally limited to 250mA, the CLC560 is fully protected against shorts to ground and can, with the addition of a series limiting resistor at the output, withstand shorts to the ±15V supplies.

The CLC560 has been designed for maximum flexibility in a wide variety of demanding applications. The two resistors comprising the feedback network set both the gain and the output impedance, without requiring the series backmatch resistor needed by most op amps. This allows driving into a matched load without dropping half the voltage swing through a series matching resistor. External compensation allows user adjustment of the frequency response. The CLC560 is specified for both maximally flat frequency response and 0% pulse overshoot compensations.

The combination of wide bandwidth, high output power, and low distortion, coupled with gain, output impedance and frequency response flexibility, makes the CLC560 ideal for waveform generator applications. Excellent stability driving capacitive loads yields superior performance driving ADC's, long transmission lines, and SAW devices. A companion part, the CLC561, offers higher full power bandwidth for broadband sinusoidal applications.

The CLC560 is constructed using thin film resistor/bipolar transistor technology. The CLC560AI is specified over a temperature range of −25°C to +85°C, while the CLC560AI8C is specified over a range of −55°C to +125°C and is fully compliant with MIL-STD-883, Level B. Both devices are packaged in 24-pin, 600 mil wide, ceramic DIPs. The DESC SMD number is 5962-90756.

FEATURES:
• 120MHz bandwidth at +24dBm output
• low distortion (2nd/3rd:
  -60/-62dBc @ 20MHz and 10dBm)
• output short circuit protection
• user-definable output impedance, gain, and compensation
• internal current limiting

NOTES TO THE ELECTRICAL SPECIFICATIONS

The electrical characteristics shown here apply to the specific test conditions shown above (see also Figure 1 in description of the operation). The CLC560 provides an equivalent, non-zero, output impedance determined by the external resistors. The signal gain to the load is therefore load dependent. **The signal gain shown above \((A_v = +10)\) is the no load gain.** The actual gain to the matching 50 ohm load used in these specifications is half of this (+5).

The CLC560 requires an external compensation capacitor. Unless otherwise noted, this has been set to 10.5pF for the frequency domain specifications (yielding a maximally flat frequency response) and 12.5pF for the time domain specifications (yielding a 0% small signal pulse overshoot response).

Parameters preceded by an * are the final electrical test parameters and are 100% tested at 25°C on all versions. The A8C grade part is also 100% tested at -55°C and 125°C case temperature.

SUMMARY DESIGN EQUATIONS AND DEFINITIONS

R_t = (G + 1) R_o - A_v R_i
R_t = Feedback resistor from output to inverting input

R_g = R_t - R_o
A_v - 1
R_g = Gain setting resistor from inverting input to ground

C_x = \frac{1}{R_o \left( 1 - \frac{2}{R_g} \right)} - .08
C_x = External compensation capacitor from output to pin 19 (in pF)

Where:
R_o = Desired equivalent output impedance
A_v = Non-inverting input to output voltage gain with no load
G = Internal current gain from inverting input to output = 10 ± 1%
R_i = Internal inverting input impedance
= 14Ω ± 5%

and
R_s = Non-inverting input termination resistor
R_L = Load Resistor
A_L = Voltage gain from non-inverting input to load resistor

CLC560 Description of Operation
Looking at the circuit of Figure 1 (the topology and resistor values used in setting the data sheet specifications), the CLC560 appears to bear a strong external resemblance to a classical op amp. As shown in the simplified block diagram of Figure 2, however, it differs in several key areas. Principally, the error signal is a current into the inverting input (current feedback) and the forward gain from this current to the output is relatively low, but very well controlled, current gain. The CLC560 has been intentionally designed to have a low internal gain and a current mode output in order that an equivalent output impedance can be achieved without the series matching resistor more commonly required of low output impedance op amps. Many of the benefits of a high loop gain have, however, been retained through a very careful control of the CLC560’s internal characteristics.

The feedback and gain setting resistors determine both the output impedance and the gain. R_t predominately sets the output impedance (R_o), while R_g predominately determines the no load gain (A_v). Solving for the required R_t and R_g, given a desired R_o and A_v, yields the design equations shown below. Conversely, given an R_t and R_g, the performance equations show that both R_t and R_g play a part in setting R_o and A_v. Independent R_o and A_v adjustment would be possible if the inverting input impedance (R_i) were 0 but, with R_i = 14Ω as shown in the specification listing, independent gain and output impedance setting is not directly possible.

Resistor Values shown result in:
R_o = 50Ω
A_v = +10
(no-load gain)
A_L = +5[14dB]
(gain to 50Ω load)

Figure 1: Test Circuit

Design Equations
R_t = (G + 1) R_o - A_v R_i
R_g = \frac{R_t - R_o}{A_v - 1}

Performance Equations
R_o = \frac{R_t + R_i \left( 1 + \frac{R_i}{R_g} \right)}{G + 1 + \frac{R_i}{R_g}}

A_v = 1 + \frac{R_t}{R_g} \left[ \frac{G - \frac{R_i}{R_g}}{G + 1 + \frac{R_i}{R_g}} \right]

Simplified Circuit Description
Looking at the CLC560’s simplified schematic in Figure 2, the amplifier’s operation may be described. Going from the non-inverting input at pin 8 to the inverting input at pin 18, transistors Q1 - Q4 act as an open loop unity gain buffer forcing the inverting node voltage to follow the non-inverting voltage input.
Transistors Q3 and Q4 also act as a low impedance (14Ω looking into pin 18) path for the feedback error current. This current, \(i_{\text{err}}\), flows through those transistors into a very well defined current mirror having a gain of 10 from this error current to the output. The current mirror outputs act as the amplifier output.

The input stage bias currents are supply voltage independent. Since these set the bias level for the whole part, relatively constant performance over supply voltage is achieved. A current sense in the error current leg of the 10X current mirror feeds back to the bias current setup providing a current shutdown feature when the output current approaches 250mA.

![Figure 2: Simplified Circuit Diagram](image)

Get both \(V_o\) and \(I_o\) into terms of just the error current, \(i_{\text{err}}\), using

\[
V^- = i_{\text{err}} R_l \quad \text{and} \quad i_r = i_{\text{err}} + \frac{V^-}{R_g} = i_{\text{err}} \left(1 + \frac{R_l}{R_g}\right)
\]

\[
V_o = V^- + i_r R_l = i_{\text{err}} \left[R_l + R_l \left(1 + \frac{R_l}{R_g}\right)\right]
\]

and

\[
I_o = G i_{\text{err}} + i_r = i_{\text{err}} \left[G + 1 + \frac{R_l}{R_g}\right]
\]

then

\[
R_o = \frac{V_o}{I_o} = \frac{R_l + R_l \left(1 + \frac{R_l}{R_g}\right)}{G + 1 + \frac{R_l}{R_g}}
\]

note that \(R_o\) simplifies considerably if \(R_l = 0\). Also note that if the forward current gain were to go to infinity, the output impedance would go to 0. This would be the normal op amp topology with a very high internal gain. The CLC560 achieves a non-zero \(R_o\) by setting the internal forward gain to be a low, well controlled, value.

![Figure 3: Output Impedance Derivation](image)

Developing the Performance Equations

The CLC560 is intended to provide both a controllable voltage gain from input to output as well as a controllable output impedance. It is best to treat these two operations separately with no load in place. Then, with the no-load gain and output impedance determined, the gain to the load will simply be the no-load gain attenuated by the voltage divider formed by the load and the equivalent output impedance.

Figure 3 steps through the output impedance development using an equivalent model of Figure 2. Offering an equivalent, non-zero, output impedance into a matched load allows the CLC560 to operate at lower internal voltage swings for a given desired swing at the load. This allows higher voltage swings to be delivered at the load for a given power supply voltage at lower distortion levels than an equivalent op amp needing to generate twice the voltage swing actually desired at the matched load. This improved distortion is specified and tested over a wide range as shown in the specification listing.

Developing the No-Load Gain Expression

Taking the output impedance expression as one constraint setting the external resistor values, we now need to develop the no-load voltage gain expression from the non-inverting input to the output as the other constraint. Figure 4 shows the derivation of the no load gain.
Recognize that [taking $V_i$ positive]

$$V_o = V_i + G_i R_{err}$$

Solving for $V_i$ from two directions

$$V_i = V - i_{err} R_i = (G + 1) i_{err} R_g$$

solving for $i_{err}$ from this

$$i_{err} = \frac{V_i}{(G + 1) R_g + R_i}$$

then

$$V_i = V_i - \frac{V_i R_i}{(G + 1) R_g + R_i}$$

and, substituting for $V_i$ and $i_{err}$ in the original $V_o$ expression

$$V_o = V_i - \frac{V_i R_i}{(G + 1) R_g + R_i} + \frac{G R_i V_i}{(G + 1) R_g + R_i}$$

which simplifies to

$$V_o = V_i \left[ 1 + \frac{G R_i - R_i}{(G + 1) R_g + R_i} \right]$$

pulling an $\frac{R_i}{R_g}$ out of the fraction

$$A_v = \frac{V_o}{V_i} = 1 + \frac{R_i}{R_g} \left[ \frac{G - \frac{R_i}{R_g}}{G + 1 + \frac{R_i}{R_g}} \right]$$

note that $A_v = 1 + \frac{R_i}{R_g} \left( \frac{G}{G + 1} \right)$

Figure 4: Voltage Gain Derivation

Note again that if $R_i = 0$ this expression would simplify considerably. Also, if $G$ were very large the voltage gain expression would reduce to the familiar non-inverting op amp gain equation. These two performance equations, shown below, provide a means to derive the design equations for $R_t$ and $R_g$ given a desired no load gain and output impedance. The details of that derivation may be found in Application Note OA-10.

**Performance Equations**

$$R_t + R_i \left( 1 + \frac{R_i}{R_g} \right)$$

$$R_o = \frac{G + 1 + \frac{R_i}{R_g}}{R_g}$$

$$A_v = 1 + \frac{R_i}{R_g} \left[ \frac{G - \frac{R_i}{R_g}}{G + 1 + \frac{R_i}{R_g}} \right]$$

**Design Equations**

$$R_t = (G + 1) R_o - A_v R_i$$

$$R_g = \frac{R_i - R_o}{A_v - 1}$$

Equivalent Model

Given that the physical feedback and gain setting resistors have been determined in accordance with the design equations shown above, an equivalent model may be created for the gain to the load where the amplifier block is taken as a standard op amp. Figure 5 shows this analysis model and the resulting gain equation to the load.

Figure 5: Equivalent Model

This model is used to generate the DC error and noise performance equations. As with any equivalent model, the primary intent is to match the external terminal characteristics recognizing that the model distorts the internal currents and voltages. In this case, the model would incorrectly predict the output pin voltage swing for a given swing at the load. But it does provide a simplified means of getting to the external terminal characteristics.

External Compensation Capacitor ($C_x$)

As shown in the test circuit of Figure 1, the CLC560 requires an external compensation capacitor from the output to pin 19. The recommended values described here assume that a maximally flat frequency response into a matched load is desired. The required $C_x$ varies widely with the desired value of output impedance and to a lesser degree on the desired gain. Note from Figure 2, the simplified internal schematic, that the actual total compensation ($C_i$) is the series combination of $C_x$ and the internal 10pF from pin 19 to the compensation nodes. The total compensation ($C_i$) is developed in two steps as shown below.

$$C_i = \frac{300}{R_o} \left( 1 - \frac{2.0}{R_o} \right) \text{ pF intermediate equation}$$

$$C_i = \frac{C_1}{1 + (0.02) C_1} \text{ pF total compensation}$$

4 – 10
With this total value derived, the required external \( C_x \) is developed by backing out the effect of the internal 10pF. This, and an expression for the external \( C_x \) without the intermediate steps are shown below.

\[
C_x = \frac{10 \cdot C_t}{10 - C_t}
\]

or

\[
C_x = \frac{1}{R_o \left(1 - \frac{2}{R_o}\right)} \text{ pF}
\]

300

The plot of Figure 6 shows the required \( C_x \) vs. gain for several desired output impedances using the equations shown above. Note that for lower \( R_o \)'s, \( C_x \) can get very large. But, since the total compensation is actually the series combination of \( C_x \) and 10pF, going to very high \( C_x \)'s is increasingly ineffective as the total compensation is only slightly changed. This, in part, sets the lower limits on allowable \( R_o \).

**Figure 6: External Compensation Capacitance (C_x)**

A 0% small signal overshoot response can be achieved by increasing \( C_x \) slightly from the maximally flat value. Note that this applies only for small signals due to slew rate effects coming into play for large, fast edge rates.

Beyond the nominal compensation values developed thus far, this external \( C_x \) provides a very flexible means for tailoring the frequency response under a wide variety of gain and loading conditions. It is oftentimes useful to use a small adjustable cap in development to determine a \( C_x \) suitable to the application, then fixing that value for production. An excellent 5pF to 20pF trimmer cap for this is a Sprague-Goodman part #GKX20000.

When the CLC560 is used to drive a capacitive load, such as an ADC or SAW device, the load will act to compensate the response along with \( C_x \). Generally, considerably lower \( C_x \) values are required than the earlier development would indicate. This is advantageous in that a low \( R_o \) would be desired to drive a capacitive load which, without the compensating effect of load itself, would otherwise require very large \( C_x \) values.

**Gain and Output Impedance Range**

Figure 7 shows a plot of the recommended gain and output impedances for the CLC560. Operation outside of this region is certainly possible with some degradation in performance. Several factors contribute to set this range. At very low output impedances, the required value of feedback resistor becomes so low as to excessively load the output causing a rapid degradation in distortion. The maximum \( R_o \) was set somewhat arbitrarily at 200Ω. This allows the CLC560 to drive into a 2:1 step down transformer matching to a 50Ω load. (This offers some advantages from a distortion standpoint. See Application Note OA-10 for details.)

**Figure 7: Recommended Gain and Output Impedance Range**

For a given \( R_o \), the minimum gain shown in Figure 7 has been set to keep the equivalent input noise voltage less than 4nV/√Hz. Generally, the equivalent input noise voltage decreases with higher signal gains. The high gain limit has been set by targeting a minimum \( R_{in} \) of 10Ω or a minimum \( R_f \) of 100Ω.

**Amplifier Configurations** (Additional discussion in Application Note OA-10)

The CLC560 is intended for a fixed, non-inverting, gain configuration as shown in Figure 1. The CLC561 offers an enhanced slew rate at the expense of higher long-term thermal tail in the pulse response than the CLC560. Due to its low internal forward gain, the inverting node does not present a low impedance, or virtual ground, node. Hence, in an inverting configuration, the signal’s source impedance will see a finite load whose value depends on the output loading. Inverting mode operation can be best achieved using a wideband, unity gain buffer with low output impedance, such as the CLC110, to isolate the source from this varying load. A DC level can, however, be summed into the inverting node to offset the output either for offset correction or signal conditioning. Application Note OA-10 describes this and a composite amplifier structure that enhances the DC and gain accuracy characteristics of the CLC560.
Accuracy Calculations
Several factors contribute to limit the achievable CLC560 accuracy. These include the DC errors, noise effects, and the impact internal amplifier characteristics have on the signal gain. Both the output DC error and noise model may be developed using the equivalent model of Figure 5. Generally, non-inverting input errors show up at the output with the same gain as the input signal, while the inverting current errors have a gain of simply \((R_l-R_o)\) to the output voltage (neglecting the \(R_o\) to \(R_l\) attenuation).

Output DC offset:
The DC error terms shown in the specification listing along with the model of Figure 5 may be used to estimate the output DC offset voltage and drift. Each term shown in the specification listing can be of either polarity. While the equations shown below are for output offset voltage, the same equation may be used for the drift with each term replaced by its temperature drift value shown in the specification listing.

\[
V_{os} = (I_{bn} \cdot R_s \pm V_{io}) \cdot \left(1 + \frac{R_l-R_o}{R_o}\right) \pm I_{bi} (R_l-R_o)
\]

Where: 
- \(I_{bn}\) = non-inverting bias current
- \(I_{bi}\) = inverting bias current
- \(V_{io}\) = input offset voltage

An example calculation for the circuit of Figure 1 using typical 25°C DC error terms and \(R_s = 25\Omega\) \(R_l = 50\Omega\) yields

\[
V_{io} = (5\mu A \cdot 250 \pm 2.0mV) 10 \pm 10\mu A (360\Omega) \frac{1}{2} = \pm 12.4 mV
\]

Recall that the source impedance, \(R_{so}\), includes both the terminating and signal source impedance and that the actual DC level to the load includes the voltage divider between \(R_o\) and \(R_l\). Also note that for the CLC560, as well as for all current feedback amplifiers, the non-inverting and inverting bias currents do not track each other in either magnitude or polarity. Hence, there is no meaning in an offset current specification, and source impedance matching to cancel bias currents is ineffective.

Noise Analysis:
Although the DC error terms are in fact random, the calculation shown above assumes they are all additive in a worst case sense. The effect of all the various noise sources are combined as a root sum of squared terms to get an overall expression for the spot noise voltage. The circuit of Figure 8 shows the equivalent circuit with all the various noise voltages and currents included along with their gains to the output.

To get an expression for the equivalent output noise voltage, each of these noise voltage and current terms must be taken to the output through their appropriate gains and combined as the root sum of squares.

\[
\theta_n = \sqrt{\left(\theta_{ni}^2 + (\theta_{ni} R_s)^2 + 4kT R_s\right) + \left(\theta_{i}^2 (R_l-R_o)^2\right)} \cdot \cdots
\]

\[
+ 4kT(R_l-R_o) A_v + 4kTR_o
\]

Where the \(4kT(R_l-R_o)A_v\) term is the combined noise power of \(R_s\) and \(R_l-R_o\).

It is often more useful to show the noise as an equivalent input spot noise voltage where every term shown above is reflected to the input. This allows a direct measure of the input signal to noise ratio. This is done by dividing every term inside the radical by the signal voltage gain squared. This, and an example calculation for the circuit of Figure 1, are shown below. Note that \(R_l\) may be neglected in this calculation.

\[
\theta_n = \sqrt{\frac{\theta_{ni}^2 + (\theta_{ni} R_s)^2 + 4kT R_s + \theta_{i}^2 (R_l-R_o)^2}{A_v^2}} \cdot \cdots
\]

\[
+ \frac{4kT(R_l-R_o)}{A_v} + \frac{4kTR_o}{A_v^2}
\]

For the circuit of Figure 1, the equivalent input noise voltage may be calculated using the data sheet spot noises and \(R_s = 25\Omega\), \(R_l = \infty\). Recall that \(4kT = 16E-21J\). All terms cast as \((nV/V/Hz)^2\)

\[
\theta_n = \sqrt{(2.1)^2 + (0.7)^2 + (0.632)^2 + (1.22)^2 + (0.759)^2 + (0.089)^2}
\]

\[
= 2.62nV/V/Hz
\]
Gain Accuracy (DC):
A classical op amp's gain accuracy is principally set by the accuracy of the external resistors. The CLC560 also depends on the internal characteristics of the forward current gain and inverting input impedance. The performance equations for $A_v$ and $R_o$ along with the Thevenin model of Figure 5 are the most direct way of assessing the absolute gain accuracy. Note that internal temperature drifts will decrease the absolute gain slightly as the part warms up. Also note that the parameter tolerances affect both the signal gain and output impedance. The gain tolerance to the load must include both of these effects as well as any variation in the load. The impact of each parameter shown in the performance equations on the gain to the load ($A_L$) is shown below.

Increasing current gain $G$ Increases $A_L$
Increasing inverting input $R_i$ Decreases $A_L$
Increasing $R_f$ Increases $A_L$
Increasing $R_g$ Decreases $A_L$

Applications Suggestions
Driving a capacitive load:
The CLC560 is particularly suitable for driving a capacitive load. Unlike a classical op amp (with an inductive output impedance), the CLC560's output impedance, while starting out real at the programmed value, goes somewhat capacitive at higher frequencies. This yields a very stable performance driving a capacitive load. The overall response is limited by the (1/RC) bandwidth set by the CLC560's output impedance and the load capacitance. It is therefore advantageous to set a low $R_o$ with the constraint that extremely low $R_f$ values will degrade the distortion performance. $R_o = 25\Omega$ was selected for the data sheet plots. Note from distortion plots into a capacitive load that the CLC560 achieves better than 60dBc THD (10 bits) driving 2Vpp into a 50pF load through 30MHz.

Improving the output impedance match vs. frequency – Using $R_x$:
Using the loop gain to provide a non-zero output impedance provides a very good impedance match at low frequencies. As shown on the Output Return Loss plot, however, this match degrades at higher frequency. Adding a small external resistor in series with the output, $R_x$, as part of the output impedance (and adjusting the programmed $R_o$ accordingly) provides a much better match over frequency. Figure 9 shows this approach.

Interpreting the Slew Rate:
The slew rate shown in the data sheet applies to the voltage swing at the load for the circuit of Figure 1. Twice this value would be required of a low output impedance amplifier using an external matching resistor to achieve the same slew rate at the load.

Layout Suggestions:
The fastest fine scale pulse response settling requires careful attention to the power supply decoupling. Generally, the larger electrolytic capacitor ground connections should be as near the load ground (or cable shield connection) as is reasonable, while the higher frequency ceramic de-coupling caps should be as near the CLC560's supply pins as possible to a low inductance ground plane.

Evaluation Boards and Encased Versions:
An evaluation board (showing a good high frequency layout) for the CLC560 is available. This board may be ordered as part #730019. In addition, encased versions of the CLC560 are also available. These are modular amplifiers similar to Comlinear's other E-series parts.

Thermal Analysis and Protection
A thermal analysis of a chip and wire hybrid is directed at determining the maximum junction temperature of all the internal transistors. From the total internal power dissipation, a case temperature may be developed using the ambient temperature and the case to ambient thermal impedance. Then, each of the dominant power dissipating paths are considered to determine which has the maximum rise above case temperature.

The thermal model and analysis steps are shown below. As is typical, the model is cast as an electrical model where the temperatures are voltages, the power dissipaters are current sources, and the thermal impedences are resistances. Refer to the summary design equations and Figure 1 for a description of terms.
\[ I_0 = \frac{V_{cc}}{R_{eq}} \] total output current

with \[ R_{eq} = R_L \parallel \left( \frac{R_I A_L}{A_L - 1} \right) \] total load

\[ I_t = \frac{1}{2} (I_o + \sqrt{I_o^2 + (0.06)^2}) \] total internal output stage current

\[ P_I = I_t (V_{cc} - V_o - 7 - 15.3 \Omega \cdot I_t) \] output stage power

\[ P_q = 0.2 \cdot I_t \cdot (V_{cc} - 1.4 - 17.3\Omega \cdot I_t) \]

power in hottest internal junction prior to output stage

\[ P_{\text{circuit}} = 1.3 \cdot V_{cc} \cdot (2 \cdot I_t - I_o + 19.2mA) - P_I - P_q \]

power in remainder of circuit [note \( V_{cc} = | - V_{cc} | \)]

Note that the \( P_I \) and \( P_q \) equations are written for positive \( V_o \). Absolute values of \( -V_{cc}, V_o, \) and \( I_o \) should be used for a negative going \( V_o \) since we are only interested in delta \( V \)'s. For bipolar swings, the two powers for each output polarity are developed as shown above then ratioed by the duty cycle. Having the total internal power, as well as its component parts, the maximum junction temperature may be computed as follows.

\[ T_c = T_A + (P_q + P_I + P_{\text{circuit}}) \cdot 0_{ca} \]

Case Temperature

\[ 0_{ca} = 35°C/W \] for the CLC560 with no heatsink in still air

\[ T_I(t) = T_o + P_I \cdot 20°C/W \]

output transistor junction temperature

\[ T_I(q) = T_c + P_q \cdot 200°C/W \]

hottest internal junction temperature

The Limiting Factor for Output Power is Maximum Junction Temperature

Reducing \( 0_{ca} \) through either heatsinking and/or airflow can greatly reduce the junction temperatures. One effective means of heatsinking the CLC560 is to use a thermally conductive pad under the part from the package bottom to a top surface ground plane on the component side. Tests have shown a \( 0_{ca} \) of 24°C in still air using a "Sil Pad" available from Bergquist (800-347-4572) as Comlinear part #550006.

As an example of calculating the maximum internal junction temperatures, consider the circuit of Figure 1 driving \( \pm 2.5V \), 50% duty cycle, square wave into a 50Ω load.

\[ R_{eq} = \frac{50\Omega \parallel \left( \frac{410\Omega \cdot 5}{5 - 1} \right)} = 45.6\Omega \]

\[ I_o = 2.5V/(45.6\Omega) = 54.9mA \]

\[ I_t = \frac{1}{2}(54.9mA + \sqrt{(54.9mA)^2 + (0.06)^2}) = 68.1mA \]

\[ P_I = 68.1mA \cdot [15 - 2.5 - 7 - 15.3\Omega \cdot 68.1mA] = 733mW \]

total power in both sides of the output stage

\[ P_q = 0.2 \cdot 68.1mA \cdot [15 - 1.4 - 17.3\Omega \cdot 68.1mA] = 169mW \]

total power in both sides of hottest junctions prior to output stage

\[ P_{\text{circuit}} = 1.3 \cdot 15 \cdot [2 \cdot 68.1mA - 54.9mA + 19.2mA] - 733mW - 169mW = 1.058W \]

power in the remainder of circuit

With these powers and \( T_A = 25°C \) and \( 0_{ca} = 35°C/W \)

\[ T_c = 25°C + (0.733 + 0.169 + 1.058) \cdot 35 = 94°C \]

case temperature

From this, the hottest internal junctions may be found as

\[ T_I(t) = 94°C + \frac{1}{2}(0.733) \cdot 20 = 101°C \] output stage

\[ T_I(q) = 94°C + \frac{1}{2}(0.169) \cdot 200 = 111°C \]

hottest internal junction

Note that \( \frac{1}{2} \) of the total \( P_I \) and \( P_q \) powers were used here since the 50% duty cycle output splits the power evenly between the two halves of the circuit whereas the total powers were used to get case temperature.

Even with the output current internally limited to 250mA, the CLC560's short circuiting capability is principally a thermal issue. Generally, the CLC560 can survive short duration shorts to ground without any special effort. For protection against shorts to the \( \pm 15 \) volt supply voltages, it is very useful to reduce some of the voltage across the output stage transistors by using some external output resistance, \( R_x \), as shown in Figure 9. Application Note OA-10 discusses this in detail.

Evaluation Board

An evaluation board (part number 730019) for the CLC560 is available.
APPLICATIONS:
• output amplification
• arbitrary waveform generation
• ATE systems
• cable/line driving
• function generators
• SAW drivers
• flash A/D driving and testing

DESCRIPTION:
The CLC561 is a wideband dc coupled, amplifier that combines high output drive and low distortion. At an output of +24dBm (10Vpp into 50Ω), the -3dB bandwidth is 150MHz. As illustrated in the table below, distortion performance remains excellent even when amplifying high-frequency signals to high output power levels.

Typical Distortion Performance

With the output current internally limited to 250mA, the CLC561 is fully protected against shorts to ground and can, with the addition of a series limiting resistor at the output, withstand shorts to the ±15V supplies.

The CLC561 has been designed for maximum flexibility in a wide variety of demanding applications. The two resistors comprising the feedback network set both the gain and the output impedance, without requiring the series backmatch resistor needed by most op amps. This allows driving into a matched load without dropping half the voltage swing through a series matching resistor. External compensation allows user adjustment of the frequency response. The CLC561 is specified for both maximally flat frequency response and 0% pulse overshoot compensations.

The combination of wide bandwidth, high output power, and low distortion, coupled with gain, output impedance and frequency response flexibility, makes the CLC561 ideal for waveform generator applications. Excellent stability driving capacitive loads yields superior performance driving ADC’s, long transmission lines, and SAW devices. A companion part, the CLC560, offers superior pulse fidelity for high accuracy dc coupled applications.

The CLC561 is constructed using thin film resistor/bipolar transistor technology. The CLC561AI is specified over a temperature range of -25°C to +85°C, while the CLC561A8C is specified over a range of -55°C to +125°C and is fully compliant with MIL-STD-883, Level B. Both devices are packaged in 24-pin, 600 mil wide, ceramic DIPs. Contact Comlinear for DESC SMD number.

FEATURES:
• 150MHz bandwidth at +24dBm output
• low distortion (2nd/3rd: -59/-62dBc @ 20MHz and 10dBm)
• output short circuit protection
• user-definable output impedance, gain, and compensation
• internal current limiting
**NOTES TO THE ELECTRICAL SPECIFICATIONS**

The electrical characteristics shown here apply to the specific test conditions shown above (see also Figure 1 in description of operation). The CLC561 provides an equivalent, non-zero, output impedance determined by the external resistors. The signal gain to the load is therefore load dependent. **The signal gain shown above \( A_v = +10 \) is the no load gain.** The actual gain to the matching 50 ohm load used in these specifications is half of this \( (+5) \).

The CLC561 requires an external compensation capacitor. Unless otherwise noted, this has been set to 10.5pF for the frequency domain specifications (yielding a maximally flat frequency response) and 12.5pF for the time domain specifications (yielding a 0% small signal pulse overshoot response).

Parameters preceded by an * are the final electrical test parameters and are 100% tested at 25°C on all versions. The A8C (military) grade part is also 100% tested at -55°C and 125°C case temperature.

SUMMARY DESIGN EQUATIONS AND DEFINITIONS

\[ R_i = (G + 1) R_o - A_v R_i \]

\[ R_o = \frac{R_f - R_o}{A_v - 1} \]

\[ C_x = \frac{1}{300 \left( 1 - \frac{2}{R_g} \right)} \]

\[ C_x = \text{External compensation capacitor from output to pin 19 (in pF)} \]

Where:

- \( R_o \) - Desired equivalent output impedance
- \( A_v \) - Non-inverting input to output voltage gain with no load
- \( G \) - Internal current gain from inverting input to output = 10 \( \pm 1 \)%
- \( R_i \) - Internal inverting input impedance = 14Ω \( \pm 5 \)%

and

- \( R_s \) - Non-inverting input termination resistor
- \( R_L \) - Load Resistor
- \( A_L \) - Voltage gain from non-inverting input to load resistor

CLC561 Description of Operation

Looking at the circuit of Figure 1 (the topology and resistor values used in setting the data sheet specifications), the CLC561 appears to bear a strong external resemblance to a classical op amp. As shown in the simplified block diagram of Figure 2, however, it differs in several key areas. Principally, the error signal is a current into the inverting input (current feedback) and the forward gain from this current to the output is relatively low, but very well controlled, current gain. The CLC561 has been intentionally designed to have a low internal gain and a current mode output in order that an equivalent output impedance can be achieved without the series matching resistor more commonly required of low output impedance op amps. Many of the benefits of a high loop gain have, however, been retained through a very careful control of the CLC561’s internal characteristics.

The feedback and gain setting resistors determine both the output impedance and the gain. \( R_f \) predominately sets the output impedance \( (R_o) \), while \( R_g \) predominately determines the no load gain \( (A_v) \). Solving for the required \( R_f \) and \( R_g \), given a desired \( R_o \) and \( A_v \), yields the design equations shown below. Conversely, given an \( R_f \) and \( R_g \), the performance equations show that both \( R_f \) and \( R_g \) play a part in setting \( R_o \) and \( A_v \). Independent \( R_f \) and \( A_v \) adjustment would be possible if the inverting input impedance \( (R_i) \) were 0 but, with \( R_i = 14\Omega \) as shown in the specification listing, independent gain and output impedance setting is not directly possible.

\[ R_f = (G + 1) R_o - A_v R_i \]

\[ R_g = \frac{R_f - R_o}{A_v - 1} \]

\[ C_x = \frac{1}{300 \left( 1 - \frac{2}{R_g} \right)} \]

\[ C_x = \text{External compensation capacitor from output to pin 19 (in pF)} \]

Where:

- \( G \) = forward current gain = 10
- \( R_i \) = inverting node input resistance = 14Ω
- \( R_o \) = desired output impedance
- \( A_v \) = desired non-inverting voltage gain with no load

Performance Equations

\[ R_o = \frac{R_i + R_f \left( 1 + \frac{R_i}{R_g} \right)}{G + 1 + \frac{R_i}{R_g}} \]

\[ A_v = 1 + \frac{R_i}{R_g} \left[ \frac{G - \frac{R_i}{R_f}}{G + 1 + \frac{R_i}{R_g}} \right] \]

Simplified Circuit Description

Looking at the CLC561’s simplified schematic in Figure 2, the amplifier’s operation may be described. Going from the non-inverting input at pin 8 to the inverting input at pin 18, transistors Q1 - Q4 act as an open loop unity gain buffer forcing the inverting node voltage to follow the non-inverting voltage input.
Transistors Q3 and Q4 also act as a low impedance (14Ω looking into pin 18) path for the feedback error current. This current, $i_{err}$, flows through those transistors into a very well defined current mirror having a gain of 10 from this error current to the output. The current mirror outputs act as the amplifier output.

The input stage bias currents are supply voltage independent. Since these set the bias level for the whole part, relatively constant performance over supply voltage is achieved. A current sense in the error current leg of the 10X current mirror feeds back to the bias current setup providing a current shutdown feature when the output current approaches 250mA.

Figure 2: Simplified Circuit Diagram

Developing the Performance Equations

The CLC561 is intended to provide both a controllable voltage gain from input to output as well as a controllable output impedance. It is best to treat these two operations separately with no load in place. Then, with the no-load gain and output impedance determined, the gain to the load will simply be the no-load gain attenuated by the voltage divider formed by the load and the equivalent output impedance.

Figure 3 steps through the output impedance development using an equivalent model of Figure 2. Offering an equivalent, non-zero, output impedance into a matched load allows the CLC561 to operate at lower internal voltage swings for a given desired swing at the load. This allows higher voltage swings to be delivered at the load for a given power supply voltage at lower distortion levels than an equivalent op amp needing to generate twice the voltage swing actually desired at the matched load. This improved distortion is specified and tested over a wide range as shown in the specification listing.

Note that the $R_o$ expression simplifies considerably if $R_i=0$. Also note that if the forward current gain were to go to infinity, the output impedance would go to 0. This would be the normal op amp topology with a very high internal gain. The CLC561 achieves a non-zero $R_o$ by setting the internal forward gain to be a low, well controlled, value.

Developing the No-Load Gain Expression

Taking the output impedance expression as one constraint setting the external resistor values, we now need to develop the no-load voltage gain expression from the non-inverting input to the output as the other constraint. Figure 4 shows the derivation of the no load gain.
Recognize that [taking $V_i$ positive]

$V_o = V_i + G_ierr R_i$

Solving for $V_-$ from two directions

$V_- = V_i - i_{err} R_i = (G+1) i_{err} R_g$

Solving for $i_{err}$ from this

$i_{err} = \frac{V_i}{(G+1) R_g + R_i}$

then

$V_- = V_i - \frac{V_i R_i}{(G+1) R_g + R_i}$

and, substituting for $V_-$ and $i_{err}$ in the original $V_o$ expression

$V_o = V_i - \frac{V_i R_i}{(G+1) R_g + R_i} + \frac{G R_i V_i}{(G+1) R_g + R_i}$

which simplifies to

$V_o = V_i \left[ 1 + \frac{G R_i - R_i}{(G+1) R_g + R_i} \right]$  

pulling an $\frac{R_f}{R_g}$ out of the fraction

$A_v = \frac{V_o}{V_i} = 1 + \frac{R_f}{R_g} \left[ \frac{G - R_i}{G + 1 + \frac{R_i}{R_g}} \right]$

note that $A_v \mid_{R_i=0} = 1 + \frac{G}{R_g}$

**Figure 4: Voltage Gain Derivation**

Note again that if $R_i = 0$ this expression would simplify considerably. Also, if $G$ were very large the voltage gain expression would reduce to the familiar non-inverting op amp gain equation. These two performance equations, shown below, provide a means to derive the design equations for $R_f$ and $R_g$ given a desired no load gain and output impedance. The details of that derivation may be found in Application Note OA-10.

**Performance Equations**

$R_o = \frac{R_f + R_i \left( \frac{R_f}{R_g} \right)}{G + 1 + \frac{R_i}{R_g}}$

$A_v = 1 + \frac{R_f}{R_g} \left[ \frac{G - R_i/R_g}{G + 1 + R_i/R_g} \right]$

**Design Equations**

$R_f = (G+1) R_o - A_v R_i$

$R_g = \frac{R_i - R_o}{A_v - 1}$

Equivalent Model

Given that the physical feedback and gain setting resistors have been determined in accordance with the design equations shown above, an equivalent model may be created for the gain to the load where the amplifier block is taken as a standard op amp. Figure 5 shows this analysis model and the resulting gain equation to the load.

$A_v = \frac{R_i}{R_L + R_o}$

Substituting in for $R_i$ and $R_g$ with their design equation yields

$V_o = A_v \frac{R_i}{R_L + R_o} = A_L$ (gain to load)

**Figure 5: Equivalent Model**

This model is used to generate the DC error and noise performance equations. As with any equivalent model, the primary intent is to match the external terminal characteristics recognizing that the model distorts the internal currents and voltages. In this case, the model would incorrectly predict the output pin voltage swing for a given swing at the load. But it does provide a simplified means of getting to the external terminal characteristics.

External Compensation Capacitor ($C_x$)

As shown in the test circuit of Figure 1, the CLC561 requires an external compensation capacitor from the output to pin 19. The recommended values described here assume that a maximally flat frequency response into a matched load is desired. The required $C_x$ varies widely with the desired value of output impedance and to a lesser degree on the desired gain. Note from Figure 2, the simplified internal schematic, that the actual total compensation ($C_t$) is the series combination of $C_x$ and the internal 10pF from pin 19 to the compensation nodes. The total compensation ($C_t$) is developed in two steps as shown below.

$\frac{C_t}{R_o} = 300 \left( 1 - \frac{2.0}{R_g} \right)$ pF intermediate equation

$C_t = \frac{C_1}{1 + (0.02) C_1}$ pF total compensation
With this total value derived, the required external $C_x$ is developed by backing out the effect of the internal 10pF. This, and an expression for the external $C_x$ without the intermediate steps are shown below.

$$C_x = \frac{10 C_t}{10 - C_t}$$

or

$$C_x = \frac{1}{R_o \left(1 - \frac{2}{R_o}\right) - .08 \text{ pF}}$$

The plot of Figure 6 shows the required $C_x$ vs. gain for several desired output impedances using the equations shown above. Note that for lower $R_o$'s, $C_x$ can get very large. But, since the total compensation is actually the series combination of $C_x$ and 10pF, going to very high $C_x$'s is increasingly ineffective as the total compensation is only slightly changed. This, in part, sets the lower limits on allowable $R_o$.

**Figure 6: External Compensation Capacitance ($C_x$)**

A 0% small signal overshoot response can be achieved by increasing $C_x$ slightly from the maximally flat value. Note that this applies only for small signals due to slew rate effects coming into play for large, fast edge rates.

Beyond the nominal compensation values developed thus far, this external $C_x$ provides a very flexible means for tailoring the frequency response under a wide variety of gain and loading conditions. It is oftentimes useful to use a small adjustable cap in development to determine a $C_x$ suitable to the application, then fixing that value for production. An excellent 5pF to 20pF trimmer cap for this is a Sprague-Goodman part #GKX20000.

When the CLC561 is used to drive a capacitive load, such as an ADC or SAW device, the load will act to compensate the response along with $C_x$. Generally, considerably lower $C_x$ values are required than the earlier development would indicate. This is advantageous in that a low $R_o$ would be desired to drive a capacitive load which, without the compensating effect of load itself, would otherwise require very large $C_x$ values.

**Gain and Output Impedance Range**

Figure 7 shows a plot of the recommended gain and output impedances for the CLC561. Operation outside of this region is certainly possible with some degradation in performance. Several factors contribute to set this range. At very low output impedances, the required value of feedback resistor becomes so low as to excessively load the output causing a rapid degradation in distortion. The maximum $R_o$ was set somewhat arbitrarily at 2000. This allows the CLC561 to drive into a 2:1 step down transformer matching to a 50Ω load. (This offers some advantages from a distortion standpoint. See Application Note OA-10 for details.)

**Figure 7: Recommended Gain and Output Impedance Range**

For a given $R_o$, the minimum gain shown in Figure 7 has been set to keep the equivalent input noise voltage less than 4nV/√Hz. Generally, the equivalent input noise voltage decreases with higher signal gains. The high gain limit has been set by targeting a minimum $R_o$ of 10Ω or a minimum $R_i$ of 100Ω.

**Amplifier Configurations** (Additional discussion in Application Note OA-10)

The CLC561 is intended for a fixed, non-inverting, gain configuration as shown in Figure 1. The CLC560 offers the better pulse fidelity with its improved thermal tail in the pulse response (vs. the CLC561). Due to its low internal forward gain, the inverting node does not present a low impedance, or virtual ground, node. Hence, in an inverting configuration, the signal’s source impedance will see a finite load whose value depends on the output loading. Inverting mode operation can be best achieved using a wideband, unity gain buffer with low output impedance, such as the CLC110, to isolate the source from this varying load. A DC level can, however, be summed into the inverting node to offset the output either for offset correction or signal conditioning. Application Note OA-10 describes this and a composite amplifier structure that enhances the DC and gain accuracy characteristics of the CLC561.
Accuracy Calculations
Several factors contribute to limit the achievable CLC561 accuracy. These include the DC errors, noise effects, and the impact internal amplifier characteristics have on the signal gain. Both the output DC error and noise model may be developed using the equivalent model of Figure 5. Generally, non-inverting input errors show up at the output with the same gain as the input signal, while the inverting current errors have a gain of simply \((R_f - R_o)\) to the output voltage (neglecting the \(R_o\) to \(R_L\) attenuation).

Output DC offset:
The DC error terms shown in the specification listing along with the model of Figure 5 may be used to estimate the output DC offset voltage and drift. Each term shown in the specification listing can be of either polarity. While the equations shown below are for output offset voltage, the same equation may be used for the drift with each term replaced by its temperature drift value shown in the specification listing.

Output DC offset:
\[
V_{os} = \left( I_{bn} \cdot R_s \pm V_{io} \right) \cdot \left( 1 + \frac{R_f - R_o}{R_o} \right) \pm I_{bi} (R_f - R_o)
\]

Where:
- \(I_{bn}\) = non-inverting bias current
- \(I_{bi}\) = inverting bias current
- \(V_{io}\) = input offset voltage

An example calculation for the circuit of Figure 1 using typical 25°C DC error terms and \(R_s = 25\Omega\) \(R_L = 50\Omega\) yields
\[
V_{o1} = \left[ (5\mu A \cdot 25\Omega \pm 2\text{mV}) \cdot 10 \pm 10\mu A (360\Omega) \right] \frac{1}{2} \approx \pm 12.4\text{mV}
\]

Recall that the source impedance, \(R_s\), includes both the terminating and signal source impedance and that the actual DC level to the load includes the voltage divider between \(R_o\) and \(R_L\). Also note that for the CLC561, as well as for all current feedback amplifiers, the non-inverting and inverting bias currents do not track each other in either magnitude or polarity. Hence, there is no meaning in an offset current specification, and source impedance matching to cancel bias currents is ineffective.

Noise Analysis:
Although the DC error terms are in fact random, the calculation shown above assumes they are all additive in a worst case sense. The effect of all the various noise sources are combined as a root sum of squared terms to get an overall expression for the spot noise voltage. The circuit of Figure 8 shows the equivalent circuit with all the various noise voltages and currents included along with their gains to the output.

![Circuit diagram](image)

Where:
- \(e_{ni}\) = non-inverting input voltage noise
- \(i_{ni}\) = non-inverting input current noise
- \(i_i\) = inverting input current noise
- \(\sqrt{4kTR_s}\) = source resistance voltage noise
- \(\sqrt{4kTR_g}\) = gain setting resistor noise current
- \(\sqrt{4kTR_f - R_o}\) = feedback resistor voltage noise
- \(\sqrt{4kTR_o}\) = output resistor voltage noise

To get an expression for the equivalent output noise voltage, each of these noise voltage and current terms must be taken to the output through their appropriate gains and combined as the root sum of squares.

\[
e_o = \sqrt{\left( e_{ni}^2 + (i_{ni}R_s)^2 + 4kTR_s \right) A_v^2 + i_i^2 (R_f - R_o)^2 + \cdots}
\]

\[
+ 4kTR_o A_v + 4kTR_o
\]

Where the \(4kT(R_f - R_o)A_v\) term is the combined noise power of \(R_g\) and \(R_f - R_o\).

It is often more useful to show the noise as an equivalent input spot noise voltage where every term shown above is reflected to the input. This allows a direct measure of the input signal to noise ratio. This is done by dividing every term inside the radical by the signal voltage gain squared. This, and an example calculation for the circuit of Figure 1, are shown below. Note that \(R_L\) may be neglected in this calculation.

\[
e_n = \sqrt{\left( e_{ni}^2 + (i_{ni}R_s)^2 + 4kTR_s + \frac{i_i^2 (R_f - R_o)^2}{A_v^2} + \cdots \right)}
\]

\[
\frac{4kTR_f - R_o}{A_v^2} + \frac{4kTR_o}{A_v^2}
\]

For the circuit of Figure 1, the equivalent input noise voltage may be calculated using the data sheet spot noises and \(R_s = 25\Omega\), \(R_f = \infty\). Recall that 4kT = 16E−21J. All terms cast as \((nV/\sqrt{Hz})^2\)

\[
e_n = \sqrt{(2.1)^2 + (0.7)^2 + (6.32)^2 + (1.22)^2 + (0.759)^2 + (0.089)^2}
\]

\[= 2.62nV/\sqrt{Hz}\]
Gain Accuracy (DC):
A classical op amp’s gain accuracy is principally set by the accuracy of the external resistors. The CLC561 also depends on the internal characteristics of the forward current gain and inverting input impedance. The performance equations for $A_L$ and $R_o$, along with the Thevinin model of Figure 5 are the most direct way of assessing the absolute gain accuracy. Note that internal temperature drifts will decrease the absolute gain slightly as the part warms up. Also note that the parameter tolerances affect both the signal gain and output impedance. The gain tolerance to the load must include both of these effects as well as any variation in the load. The impact of each parameter shown in the performance equations on the gain to the load ($A_L$) is shown below.

Increasing current gain $G$ Increases $A_L$
Increasing inverting input $R_i$ Decreases $A_L$
Increasing $R_f$ Increases $A_L$
Increasing $R_g$ Decreases $A_L$

Applications Suggestions
Driving a capacitive load:
The CLC561 is particularly suitable for driving a capacitive load. Unlike a classical op amp (with an inductive output impedance), the CLC561’s output impedance, while starting out real at the programmed value, goes somewhat capacitive at higher frequencies. This yields a very stable performance driving a capacitive load. The overall response is limited by the $(1/RC)$ bandwidth set by the CLC561’s output impedance and the load capacitance. It is therefore advantageous to set a low $R_o$ with the constraint that extremely low $R_i$ values will degrade the distortion performance. $R_o=250\ \Omega$ was selected for the data sheet plots. Note from distortion plots into a capacitive load that the CLC561 achieves better than 60dBc THD (10 bits) driving 2VPP into a 50pF load through 30MHz.

Improving the output impedance match vs. frequency – Using $R_x$:
Using the loop gain to provide a non-zero output impedance provides a very good impedance match at low frequencies. As shown on the Output Return Loss plot, however, this match degrades at higher frequency. Adding a small external resistor in series with the output, $R_x$, as part of the output impedance (and adjusting the programmed $R_o$ accordingly) provides a much better match over frequency. Figure 9 shows this approach.

Increasing $R_x$ will decrease the achievable voltage swing at the load. A minimum $R_x$ should be used consistent with the desired output match. As discussed in the thermal analysis discussion, $R_x$ is also very useful in limiting the internal power under an output shorted condition.

Interpreting the Slew Rate:
The slew rate shown in the data sheet applies to the voltage swing at the load for the circuit of Figure 1. Twice this value would be required of a low output impedance amplifier using an external matching resistor to achieve the same slew rate at the load.

Layout Suggestions:
The fastest fine scale pulse response settling requires careful attention to the power supply de-coupling. Generally, the larger electrolytic capacitor ground connections should be as near the load ground (or cable shield connection) as is reasonable, while the higher frequency ceramic de-coupling caps should be as near the CLC561’s supply pins as possible to a low inductance ground plane.

Evaluation Boards and Encased Versions:
An evaluation board (showing a good high frequency layout) for the CLC561 is available. This board may be ordered as part #730019. In addition, encased versions of the CLC561 are also available. These are modular amplifiers similar to Comlinear’s other E-series parts.

Thermal Analysis and Protection
A thermal analysis of a chip and wire hybrid is directed at determining the maximum junction temperature of all the internal transistors. From the total internal power dissipation, a case temperature may be developed using the ambient temperature and the case to ambient thermal impedance. Then, each of the dominant power dissipating paths are considered to determine which has the maximum rise above case temperature.

The thermal model and analysis steps are shown below. As is typical, the model is cast as an electrical model where the temperatures are voltages, the power dissipators are current sources, and the thermal impedances are resistances. Refer to the summary design equations and Figure 1 for a description of terms.
\[ I_o = V_o/R_{eq} \] total output current

with \[ R_{eq} = R_L \| \left( \frac{R_i A_i}{A_i - 1} \right) \] total load

\[ I_i = \frac{1}{2}(I_o + \sqrt{I_o^2 + (0.06)^2}) \] total internal output stage current

\[ P_T = I_T(V_{cc} - V_o - 7 - 15.3 \Omega \cdot I_i) \] output stage power

\[ P_q = 0.2 \cdot I_i \cdot (V_{cc} - 1 - 17.3 \Omega \cdot I_i) \] power in hottest internal junction prior to output stage

\[ P_{\text{circuit}} = 1.3 \cdot V_{cc} \cdot (2 \cdot I_i - I_o + 19.2 \text{mA}) - P_T - P_q \] power in remainder of circuit [note \( V_{cc} = |V_{cc}| \)]

Note that the \( P_T \) and \( P_q \) equations are written for positive \( V_o \). Absolute values of \( -V_{cc}, V_o, \) and \( I_o \) should be used for a negative going \( V_o \) since we are only interested in delta \( V \)'s. For bipolar swings, the two powers for each output polarity are developed as shown above then ratioed by the duty cycle. Having the total internal power, as well as its component parts, the maximum junction temperature may be computed as follows.

\[ T_c = T_A + (P_q + P_T + P_{\text{circuit}}) \cdot \theta_{CA} \] Case Temperature

\[ \theta_{CA} = 35^\circ C/W \] for the CLC561 with no heatsink in still air

\[ T_j(t) = T_c + P_T \cdot 20^\circ C/W \] output transistor junction temperature

\[ T_j(q) = T_c + P_q \cdot 200^\circ C/W \] hottest internal junction temperature

The Limiting Factor for Output Power is Maximum Junction Temperature

Reducing \( \theta_{CA} \) through either heatsinking and/or airflow can greatly reduce the junction temperatures. One effective means of heatsinking the CLC561 is to use a thermally conductive pad under the part from the package bottom to a top surface ground plane on the component side. Tests have shown a \( \theta_{CA} \) of 24°C/W in still air using a "Sil-Pad" available from Bergquist (800-347-4572) as Comlinear part #550006.

As an example of calculating the maximum internal junction temperatures, consider the circuit of Figure 1 driving ±2.5V, 50% duty cycle, square wave into a 50Ω load.

\[ R_{eq} = 50 \Omega \| \left( \frac{410 \Omega \cdot 5}{5-1} \right) = 45.6 \Omega \]

\[ I_o = 2.5V/(45.6 \Omega) = 54.9 \text{mA} \]

\[ I_T = \frac{1}{2}(54.9 \text{mA} + \sqrt{(54.9 \text{mA})^2 + (0.06)^2}) = 68.1 \text{mA} \]

\[ P_T = 68.1 \text{mA} \cdot (15 - 2.5 - 7 - 15.3 \Omega \cdot 68.1 \text{mA}) = 733 \text{mW} \] total power in both sides of the output stage

\[ P_q = 0.2 \cdot 68.1 \text{mA} \cdot (15 - 1 - 17.3 \Omega \cdot 68.1 \text{mA}) = 169 \text{mW} \] total power in both sides of hottest junctions prior to output stage

\[ P_{\text{circuit}} = 1.3 \cdot (15) \cdot (2 \cdot 68.1 \text{mA} - 54.9 \text{mA} + 19.2 \text{mA} - 733 \text{mW} - 169 \text{mW}) = 1.058 \text{W} \] power in the remainder of circuit

With these powers and \( T_A = 25^\circ C \) and \( \theta_{CA} = 35^\circ C/W \)

\[ T_c = 25^\circ C + (.733 + .169 + 1.058) \cdot 35 = 94^\circ C \] case temperature

From this, the hottest internal junctions may be found as

\[ T_j(t) = 94^\circ C + \frac{1}{2} \cdot 733 \cdot 20 = 101^\circ C \] output stage

\[ T_j(q) = 94^\circ C + \frac{1}{2} \cdot 169 \cdot 200 = 111^\circ C \] hottest internal junction

Note that \( \frac{1}{2} \) of the total \( P_T \) and \( P_q \) powers were used here since the 50% duty cycle output splits the power evenly between the two halves of the circuit whereas the total powers were used to get case temperature.

Even with the output current internally limited to 250mA, the CLC561's short circuiting capability is principally a thermal issue. Generally, the CLC561 can survive short duration shorts to ground without any special effort. For protection against shorts to the ±15 volt supply voltages, it is very useful to reduce some of the voltage across the output stage transistors by using some external output resistance, \( R_x \), as shown in Figure 9. Application Note OA-10 discusses this in detail.

Evaluation Board

An evaluation board (part number 730019) for the CLC561 is available.

**Variable Gain Amplifiers**
Comlinear Corporation

Amplifier with Voltage Controlled Gain, AGC+Amp

APPLICATIONS:
- wide-bandwidth AGC systems
- automatic signal-leveling
- video signal processing
- voltage controlled filters
- differential amplifier
- amplitude modulation

DESCRIPTION
The CLC520 is a wideband DC-coupled amplifier with voltage-controlled gain (AGC). The amplifier has a high-impedance differential signal input, a high-bandwidth gain control input and a single-ended voltage output. Signal channel performance is outstanding with 160MHz small signal bandwidth, 0.5 degree linear phase deviation (to 60MHz) and 0.04% signal nonlinearity at 4Vpp output.

Gain-control is very flexible. Maximum gain may be set over a nominal range of 2 to 100 with one external resistor. In addition, the gain-control input provides more than 40dB of voltage-controlled gain adjustment from the maximum gain setting. For example, a CLC520 may be set for a maximum gain of 2 (or 6dB) for a voltage-controlled gain range from 6dB to less than -34dB. Alternatively, the CLC520 could be set for a maximum gain of 100 (40dB) for a voltage-controlled gain range from 40dB to less than 0dB.

Besides being flexible, the gain-control is easy to use. Gain-control bandwidth is superb, 100MHz, simplifying AGC/ALC loop stabilization. And since the gain is minimum with a zero volt input and maximum with a +2 volt input, driving the control input is simple.

Finally, differential inputs, and a ground-referenced voltage output take the trouble out of designing DC-coupled AGC circuits for display normalizers, etc. The CLC520 is available in several versions:

- CLC520AJP -40°C to +85°C 14-pin plastic DIP
- CLC520AJE -40°C to +85°C 14-pin plastic SOIC
- CLC520AID -40°C to +85°C 14-pin side-brazed DIP
- CLC520A8D -55°C to +125°C 14-pin side-brazed DIP, MIL-STD-883, Level B
- CLC520ALC -55°C to +125°C dice
- CLC520AMC -55°C to +125°C dice qualified to Method 5008, MIL-STD-883, Level B

Contact factory for other packages. DESC SMD number 5962-91694.

FEATURES (typical):
- 160MHz, -3dB bandwidth
- 2000 V/µsec slew rate
- 0.04% signal nonlinearity at 4Vpp output
- -43dB feedthrough at 30MHz
- user adjustable gain range
- differential voltage input and single-ended voltage output

Linearity, \( V_g = 0.9V \) to 1.2V

Figure 1: CLC520 Simplified Schematic

Simplified Circuit Description

A simplified schematic for the CLC520 is given in Figure 1. \(+ V_{in}\) and \(- V_{in}\) are buffered with closed-loop voltage followers inducing a signal current in \( R_g \) proportional to \((+V_{in}) - (-V_{in})\), the differential input voltage. This current controls a current source which supplies two well-matched transistors, \( Q_1 \) and \( Q_2 \).

The current flowing through \( Q_2 \) is converted to the final output voltage using \( R_t \) and output amplifier, \( U_1 \). By changing the fraction of the signal current \( I \) which flows through \( Q_2 \) the gain is changed. This is done by changing the voltage applied differentially to the bases of \( Q_1 \) and \( Q_2 \). For example, \( V_g = 0 \), \( Q_1 \) conducts heavily and \( Q_2 \) is off. With none flowing through \( R_t \), the CLC520's input to output gain is strongly attenuated. With \( V_g = 2V \), \( Q_1 \) is off and all of \( I \) flows through \( Q_2 \) to \( R_t \) producing maximum gain. With \( V_g \) set to \( 1.1V \), the bases of \( Q_1 \) and \( Q_2 \) are approximately the same voltage, \( Q_1 \) and \( Q_2 \) have the same collector currents - equal to one half of signal current \( I \), thus the gain is approximately one half the maximum at \( V_g = 1.1V \).

Typical application circuit

Figure 2 illustrates a voltage-controlled gain block of broadband performance in a 50Ω system environment. An input signal is applied to pin 3 of the CLC520 and terminated by \( R_2 \). Gain-control signals are applied to pin 11. The net gain-control port input impedance is 50Ω, set by a parallel combination of \( R_1 \) and the 750Ω input impedance of pin 2 of the CLC520.

\( R_t \) is set to the standard value, 1kΩ, and \( R_g \) sets the maximum voltage gain (with a high Z load connected to it) to 10V/V. Output impedance is set by \( R_0 \) to 50Ω so with source and load terminations, the gain is approximately...
Capacitors C1-C6 provide broadband power-supply bypassing. C2 and C5 should be tantalum capacitors. All other capacitors should be high-quality ceramic capacitors (C0-05 or equivalent).

**Adjusting offset**
Offset can be broken into two parts: an input-referred and an output-referred term. The input-referred offset shows up as a variation in output voltage as \( V_0 \) is changed. This can be trimmed using the circuit in Figure 3 by placing a low frequency square wave \( (V_0 = 0V, \ V_F = 2V) \) into \( V_i \) (with \( V_i \) set to zero volts) and adjusting R1 until the CLC520 output produces a steady DC value. After adjusting the input-referred offset, adjust R2 with \( V_i = 0, \ V_o = 0 \) until \( V_o \) is zero. Finally, in inverting applications \( V_i \) may be applied to pin 6 and the offset adjustment to pin 3. This offset trim does not improve output offset temperature coefficient.

**Selecting component values**
Maximum input amplitude and maximum gain are the two key specifications that determine component values in a CLC520 application.

The output stage op amp is a current-feedback type amplifier optimized for \( R_i = 1k\Omega \). \( R_i \) can then be computed as:

\[
R_i = R_{\text{i max}} \times 1.85 - 3.0\Omega \text{ with } R_{\text{i max}} = 1k\Omega \quad (1)
\]

To determine whether the maximum input amplitude will overdrive the CLC520, compute:

\[
V_{\text{max}} = (R_{\text{i max}} + 3.0\Omega) \times 0.00135
\]

the maximum differential input voltage for linear operation.

If the maximum input amplitude exceeds this limit, the CLC520 should either be moved to a location in the signal chain where amplitudes are reduced, \( A_{\text{max}} \) should be reduced or the values for \( R_i \) and \( R_o \) should be increased.

If the input amplitude is reduced, recompute the impact of the CLC520 on signal-to-noise ratio. If \( A_{\text{max}} \) is reduced, recompute the impact of temperature on the CLC520 and optimize for \( R_i \).

**Predicting the output noise**
Seven noise sources \( (e_{\text{in}}, i_{\text{in}}, i_{\text{op}}, i_{\text{op}}, e_{\text{no}}, e_{\text{core}}, E_{\text{core}}) \) are used to model the CLC520 noise performance (Figure 4). \( e_{\text{in}}, i_{\text{in}}, \) and \( i_{\text{op}} \) model the equivalent input noise terms for the input buffer while \( i_{\text{op}}, i_{\text{op}}, \) and \( e_{\text{no}} \) model the noise terms for the output buffer. To simplify the model \( e_{\text{in}} \) includes the effect of resistor \( R_i \) (see Figure 5 for \( e_{\text{in}} \) vs \( R_i \)). To simplify the model further, \( R_{\text{bias}} \) is assumed noiseless and its noise contribution is included in \( i_{\text{op}} \).

An additional term \( E_{\text{core}} \) mimics the active device noise contribution from the Gilbert multiplier core. Core noise is theoretically zero when the multiplier is set to maximum gain or zero gain (\( V_o = 1.6V \) or \( V_o = 0.83V \) respectively at room temperature) and reaches a maximum of \( 37\text{nV/}\sqrt{\text{Hz}} \) at \( A_{\text{max}}^{\text{max}}/2 \).
The easiest way to analyze the output noise of this circuit is to break the analysis into three pieces: an input buffer noise calculation, an output buffer noise calculation, and a core noise calculation. The output contribution of the input buffer varies with the gain. The output contribution of the output buffer is constant. The core noise contribution is zero at maximum and minimum gain and reaches a peak at $A_{\text{max}}^{2}/2$. Summing the noise powers for each of these terms gives the total output noise power.

Since we assume all noise terms are uncorrelated, the equivalent input noise voltage squared is given by:

$$E_{\text{I}}^{2} = 4kT_{C} + (i_{C})^{2} + e_{n}^{2}$$

$i_{C}$ does not contribute to the input buffer noise because the input buffer inverting input is grounded. $e_{n}$ is taken from Figure 5.

The equivalent output buffer noise is given by:

$$E_{\text{out}}^{2} = (i_{o} \cdot 1k\Omega)^{2} + 4kT(1k\Omega) + [e_{no}(1 + 1k\Omega/5k\Omega)]^{2}$$

$I_{no}$ does not contribute to the output buffer noise because the output buffer non-inverting input is grounded.

The core noise is already output referred and is $37nV/\sqrt{Hz}$ at $V_{g}=1.1\ (A_{\text{max}}/2)$ and approaches zero as $A_{g}$ goes to 0 or $A_{\text{max}}$.

The total output voltage noise is given by:

$$E_{\text{TOTAL}} = E_{\text{I}}^{2} + E_{\text{out}}^{2} + C E_{\text{core}}^{2}$$

Where $A_{g}$ is the input to output voltage gain (which varies as $V_{g}$ varies).

$C$ accounts for the variation in core noise contribution as $V_{g}$ is adjusted. $C=1$ when gain $A_{g}$ is $A_{\text{max}}/2$, $C$ is zero at $A_{\text{max}}$ and $A_{g}=0$ and varies between 0 and 1 for all other values.

Using these equations, total calculated output noise for the circuit was $20nV/\sqrt{Hz}$ at minimum gain, $49nV/\sqrt{Hz}$ at mid-gain, and $53nV/\sqrt{Hz}$ at maximum gain.

AGC circuits

Figure 8 shows a typical AGC circuit. The CLC520 is followed up with a CLC401 for higher overall gain. The output of the CLC401 is rectified and fed to an inverting integrator using a CLC420 (wideband voltage feedback op amp). The output voltage $V_{\text{out}}$ is too large the integrator output voltage ramps down reducing the net gain of the CLC520 and $V_{\text{out}}$. If the output voltage is too small, the integrator ramps up increasing the net gain and the output voltage. Actual output level is set with $R_{1}$. To prevent shifts in DC output voltage with changes in input signal level, trim pot $R_{2}$ is provided. AGC circuits are always limited in the range of input signals over which constant output level can be maintained. In this circuit, we would expect that reasonable AGC action could be maintained over the gain adjustment range of the CLC520 (at least 40dB). In practice, rectifier dynamic range limits reduce this slightly.

Evaluation Board

Evaluation PC boards (part number 730029 for through-hole and 730023 for SOIC) for the CLC520 are available.

Figure 5

Several points should be made concerning this model. First, external component noise contributions need to be factored in when computing total output referred noise. The only exception is $R_{1}$ where its noise contribution is already factored in. Second, the model ignores flicker noise contributions. Applications where noise below approximately 100KHz must be considered should use this model with caution. Third this model very accurately predicts output noise performance over the normal range of $A_{\text{max}}$ and component values.

Figure 6: Typical Circuit

Figure 7: Noise Model for Typical Circuit

Calculating CLC520 output noise in a typical circuit

To calculate the noise in a CLC520 application, the noise terms given for the amplifier as well as the noise terms of the external components must be included. To clarify the techniques used, output noise in a typical circuit will be calculated. (Figure 6)

The noise model is depicted in Figure 7. The diagram assumes spot noise sources with $V_{\text{rms}}/\sqrt{Hz}$ and $Amps_{\text{rms}}/\sqrt{Hz}$ units. The Thevenin equivalent of the source and input termination is used: $25\Omega$ in series with a noise voltage source. $R_{1}$ is assumed noiseless since its effect is included in $e_{n}$. The internal $5\Omega$ resistor at the CLC520 core output is also assumed noiseless since its effect is included in $i_{o}$. The noise contribution from $R_{1}$ is modeled as a noise voltage source.
APPLICATIONS:
• high-speed analog signal processing
• RF modulators & mixers
• automatic gain control & leveling loops
• video production switching
• instrumentation
• voltage controlled filters

DESCRIPTION
The CLC522 variable gain amplifier (VGA) is a dc-coupled, two-quadrant multiplier with differential voltage inputs and a single-ended voltage output. The CLC522 is a complete VGA system which does not require external buffering since two input buffers and an output op amp are integrated with the multiplier core. Only two external resistors are needed to set the CLC522's maximum gain and gain control is easily achieved through a single high impedance voltage input. The CLC522 provides a linear in V/V relationship between the amplifier's gain and the gain-control input voltage.

The CLC522's maximum gain may be set externally over a nominal range of 2V/V to 100V/V with the gain control input providing a 40dB gain range down from the maximum setting. For example, set for a maximum gain of 10V/V, the CLC522 will provide a 100V/V to 1V/V gain control range by sweeping the gain control input through its full scale range of +1V to -1V.

Set at a maximum gain of 10V/V, the CLC522 provides a 165MHz signal channel bandwidth and a 165MHz gain control bandwidth. Gain nonlinearity over the full 40dB gain range is 0.5% and gain accuracy at the maximum gain of 10V/V is typically ±0.3%.

The CLC522 is available in the following versions.

- CLC522AJP -40°C to +85°C 14-pin Plastic DIP
- CLC522AJE -40°C to +85°C 14-pin Plastic SOIC
- CLC522AIB -40°C to +85°C 14-pin CERDIP
- CLC522A8B -55°C to +125°C 14-pin CERDIP, MIL-STD-883, Level B
- CLC522A8L-2 -55°C to +125°C 20-pin LCC, MIL-STD-883, Level B
- CLC522ALC -55°C to +125°C dice, MIL-STD-883, Level B
- CLC522AMC -55°C to +125°C dice, MIL-STD-883, Level B

Designing with the CLC522

The CLC522 is a wideband variable gain amplifier. A voltage input signal may be applied differentially between the two inputs, or single-ended by grounding the unused differential input (see figure 1, Typical application circuit). The CLC522 input buffers convert the input voltage to a current. This current is a function of the input voltage and the value of $R_g$, the gain-setting resistor. A voltage-controlled two-quadrant multiplier attenuates this current. The multiplier output current is then converted to a voltage via the output amplifier. This output amplifier is a current feedback amplifier configured as a transimpedance amplifier. The transimpedance gain is the feedback resistor, $R_f$. The input signal, output, and gain control are all voltages.

The maximum gain is a function of the ratio, $R_f/R_g$, more specifically,

$$G_{\text{max}} = \frac{R_f \cdot 1.85}{R_g + 3\Omega}$$

Eq. 1

The maximum input voltage, $V_{d\text{max}}$, which can be accommodated by the V-I conversion of the input buffers is a function of $R_g$,

$$V_{d\text{max}} = (R_g + 3\Omega) \cdot 1.35\text{mA}$$

Eq. 2

The 1.35mA is the minimum guaranteed current available in the V-I converter. Typically this current is 1.75mA.

Comparing equations 1 and 2, it can be seen that the maximum available gain, $G_{\text{max}}$, is inversely proportional to $R_g$. The maximum input voltage for linear operation, $V_{d\text{max}}$, is directly proportional to $R_g$. Large maximum gains with large input signals are possible when all factors affecting the CLC522 performance are understood.
The effect of $R_g$ on both $G_{max}$ and $V_{dmax}$ suggests the following design procedure to get the most out of the CLC522. First, $R_g$ is determined based on the maximum input signal. $V_{dmax}$ is a peak voltage. Once this maximum peak input voltage is known, $R_g$, in ohms, is calculated:

$$R_g = \frac{V_{dmax}}{1.35m\Omega} - 3\Omega \tag{Eq. 3}$$

This value of $R_g$ is then used to calculate $R_I$, in ohms:

$$R_I = \frac{G_{max}(R_g + 3\Omega)}{1.85} \tag{Eq. 4}$$

Since the output amplifier is a current feedback amplifier, the value of $R_I$ has a profound affect on the small-signal bandwidth and stability of a current feedback amp. A complete discussion of the feedback resistor's influence on the performance of current feedback amps can be found in OA-20, "Current Feedback Myths Debunked", and OA-13, "Current Feedback Loop Gain Analysis and Performance Enhancements". A first-order approximation would be that doubling the value of the recommended $R_I$ cuts the bandwidth in half.

The value of $R_I$ calculated from equation 4 must then be reviewed for its effect on circuit bandwidth and stability. $R_I$ less than 1$k\Omega$ is not recommended, except for high $G_{max}$. This datasheet uses an $R_I$ of 715$k\Omega$ for $G_{max} = 100V/V$. Higher $R_I$ will reduce bandwidth. This can be seen in the typical plots. If the resulting values of $R_I$ and $R_g$ reduce bandwidth excessively, the design goals must be reconsidered. $R_g$ can be reduced if the maximum input voltage requirement is relaxed.

Typically a conflict arises in designs with large input signals and large maximum gain. An example is an input dynamic range of 40dB ($V_{in}(\text{peak}) = 1V$ to 10mV) with a desired constant output of 1V(peak). In this case the gain must range from a minimum of 1/V (unity gain when $V_{in} = 1V$) to a maximum of 100/V (40dB for $V_{in} = 10mV$). In this case $R_g = 738\Omega$, $R_I = 40k\Omega$. A feedback resistor large is not practical for noise reasons, and will severely limit the bandwidth of the CLC522. If the input-to-output dynamic range requirement can be reduced to 20dB ($G_{max} = 10V/V$), $R_I$ is then 4kΩ. These circuit values will yield a constant output voltage of 100mV, with an approximate bandwidth of 40MHz. A constant gain-of-10V/V amplifier can follow the CLC522 for the desired final output voltage of 1V. The recommended values for $G_{max} = 10V/V$ are $R_g = 182\Omega$ and $R_I = 1k\Omega$. These values result in a circuit with a small-signal bandwidth of 165MHz and a maximum input voltage of 250mV(peak).

Printed Circuit Layout

A good high-frequency PCB layout including ground plane and power supply bypassing are essential for optimum performance. The amplifier is sensitive to stray capacitance to ground at the input (pin 12); keep trace area small and remove ground plane near the input pins. Shunt capacitance across $R_I$ must not be used to compensate for this effect as is often done with voltage feedback op-amps. Keep in mind that ground plane beneath $R_I$ will add undesirable shunt capacitance, as well as capacitance to ground.

Symmetric traces from $R_g$ to pins 4 and 5 will yield the best results. Capacitance to ground can be minimized by removing ground plane from under the body of $R_g$.

High-frequency ceramic bypass capacitors must be used on each of the five power supply pins (1, 13, 14, 7, 8). The $-V_{CC}$ pin is particularly important in this respect. The signal gain is determined by the difference in potential between $V_g$ (pin 2) and $-V_{CC}$ on pin 7. Any variation in the voltage on pin 7 will translate directly to a change in gain.

Parasitic or load capacitance, $C_I$ on the output (pin 10) degrades phase margin and can lead to frequency response peaking. A small series resistor between pin 10 and $C_I$ decouples this effect (see the plot “Settling Time vs. Capacitive Load for a Recommended $R_{in}$”).

The non-inverting input of the output op-amp (pin 9) must be kept near ground potential. A 20Ω resistor to ground improves the frequency response of this amp. It does not, however, improve offsets due to bias current effects.

Adjusting Offset

![Figure 7: Input and output stage DC nulling](image)

The output stage offset should be trimmed prior to the input stage. With the gain adjust pin set at minimum gain (maximum attenuation), the output stage offset may be nullled independently from the input stage. $R_{14}$ should be adjusted to yield the desired output error voltage (typically <1mV). Having corrected for the input offset voltage and bias current errors of the output amplifier, returning the gain adjust pin to the maximum gain voltage will allow the input buffer stage DC offset errors to be corrected. With no input signal present, but with matched source impedances at each of the two buffer inputs, $R_{10}$ of Figure 7 can be adjusted to bring the output within the desired error band.
Adjusting the input and the output stage offsets at the two gain extremes will hold the output DC error at a minimum at these two points in the gain range. If a more limited gain range is anticipated, the adjustments should be made at these operating points. The non-linear DC error introduced by the multiplier core will cause a residual, gain dependent, offset to appear at the output as the gain is swept from minimum to maximum. Also, neither the input nor the output offset adjustments described here will improve temperature drift effects. For more information, contact Comlinear Corporation for the final data sheet.

Evaluation PC boards, part numbers 730029 (through-hole) and 730033 (surface mount) are available from Comlinear at minimal cost.

Design Equations:

\[
A_{\text{max}} = R_g + 3.0
\]

\[
A_v = \frac{A_{\text{max}}}{2}(V_g + 1)
\]

\[
V_{\text{out}} = (R_g + 3.0) \times 0.00135
\]

Where:

\[
A_v = \frac{(+V_{\text{in}})(-V_{\text{in}})}{2}
\]

\[
A_{\text{max}} = \text{maximum gain}
\]

\[
R_v = \text{feedback resistor, } R_g = \text{gain resistor}
\]

\[
V_{\text{out}} = \text{maximum differential voltage}
\]

Notes:

The recommended value of \( R_v \) is 1kΩ. It is recommended that the value of the gain setting resistor \( R_g \) be adjusted to change the maximum gain \( A_{\text{max}} \). The recommended range of \( A_{\text{max}} \) is ±2 to ±100.

The input buffers are current limited. Consequently, the maximum differential input voltage range \( V_{\text{max}} \) that is guaranteed for linear operation, is proportional to the value chosen for \( R_g \) (given in the equation above).

Unity Gain Buffer and Linear Amplifiers

Contents
APPLICATIONS:

- digital and wideband analog communications
- radar, IF and RF processors
- fiber optic drivers and receivers
- photomultiplier preamplifiers

DESCRIPTION

Comlinear Corporation's CLC104 Linear Amplifier represents a significant advance in linear amplifiers. Proprietary design techniques have yielded an amplifier with 14dB of gain and a -3dB bandwidth of DC to 1100MHz. Gain flatness to 750MHz of ±0.4dB coupled with excellent VSWR and phase linearity gives outstanding pulse fidelity and low signal distortion.

Designed for 50Ω systems, the CLC104 is very easy to use, requiring only properly bypassed power supplies for operation. This translates to time- and cost-savings in all stages of design and production.

Fast rise time, low overshoot and linear phase make the CLC104 ideal for high speed pulse amplification. These properties plus low distortion combine to produce an amplifier well suited to many communications applications. With a 1.1GHz bandwidth, the CLC104 can handle the fastest digital traffic, even when the demodulation scheme or the digital coding format requires that DC be maintained. It is also ideal for traditional video amplifier applications such as radar or wideband analog communications systems.

These same characteristics make the CLC104 an excellent choice for use in fiber optics systems, on either the transmitting or receiving end of the fiber. The low group delay distortion insures that pulse integrity will be maintained. As a photomultiplier tube preamp, its fast response and quick overload recovery provide for superior system performance.

The CLC104 is constructed using thin film resistor/bipolar transistor technology. The CLC104AI is specified over a temperature range of -25°C to +85°C. The device is packaged in a 14-pin double-wide DIP package.

FEATURES:

- -3dB bandwidth of 1.1GHz
- 325psec rise and fall times
- 14dB gain, 50Ω input and output
- low distortion, linear phase
- 1.4:1 VSWR (output, DC-1.1GHz)

2. (Input bias current) X (R<sub>i</sub>) (50Ω) = input offset voltage
3. Output offset can be adjusted to zero with an external potentiometer – see "Reducing DC Offset"
4. * = final electrical test parameter, 100% tested at 25°C
PC Board Layout Considerations

Proper layout of printed circuit boards is important to achieve optimum performance of a circuit operating in the 1GHz frequency range. Use of microstrip line is recommended for all signal-carrying paths and low resistance, low inductance signal return and bypass paths should be used. To keep the impedance of these paths low, use as much ground plane as is possible. Ground plane also serves to increase the flow of heat out of the package.

The CLC104 has three types of connections: signal paths (input and output), DC inputs (supplies and offset adjust), and grounds. 50Ω microstrip is recommended for connection to the input (pin 4) and output (pin 11). Microstrip on a double-sided PC board consists of a ground plane on one side of the board and a constant-width signal-carrying trace on the other side of the board. For 1/16" G10 or FR-4 PC board material, a 0.1" wide trace will have a 50Ω characteristic impedance. The ground plane beneath the signal trace must extend at least one trace width on either side of the trace. Also, all traces (including ground) should be kept at least one trace width from the signal carrying traces.
To keep power supply noise and oscillations from appearing at the amplifier output, all supply pins should be capacitively bypassed to ground. The power supply pins (1 and 2) are the inputs to a pair of voltage regulators whose outputs are at pins 13 and 14. It is recommended that 0.01µF or larger ceramic capacitors be connected from pins 1, 2, 13 and 14 to ground, within 0.2" of the pins. A 1µF or larger solid tantalum capacitor to ground is required within 3" of pins 1 and 2, and for good low frequency performance, solid tantalum capacitors of at least 15µF should be connected from pins 13 and 14 to ground within 3" of the pins. Use 0.025" or wider traces for the supply lines. The offset adjust pin (12) also requires bypassing a 0.01µF or larger ceramic capacitor to ground within 0.2" of the pin is recommended.

Grounding is the final layout consideration. Pins 3 and 5-10 should all be connected to a ground plane which should cover as much of one side of the board around the amplifier as possible.

Reducing DC Offset

DC offset of the CLC104 may be adjusted by applying a DC voltage to the amplifier’s offset adjust pin (12). The simplest method is shown in Figure 1. Using this method of offset adjust it is possible to vary the output offset by approximately ±400mV. This simple adjustment has no effect on the offset drift characteristics of the CLC104.

If lower offset and offset drift are required, a low frequency op amp may be used in conjunction with the CLC104 in a composite configuration. The suggested circuit appears in Figure 2. Its method of operation is to compare an attenuated version of the output signal to the input signal and apply a correcting voltage at the offset adjust pin. A compensation capacitor Cx reduces the bandwidth of the op amp correction circuit to limit the op amp’s effect on the CLC104 to frequencies below fxe, the frequency at which the op amp has 45dB of open loop gain. Using an LM108, fxe is about 7Hz with Cx = 1µF. Thus the op amp can correct DC and low frequency errors below fxe, without affecting CLC104 performance above fxe. Also note that the noise performance of the op amp will dominate below fxe.

With an LM108 op amp in this composite configuration, input offset is typically 2mV and drift is 15µV/°C. At frequencies well below fxe, the composite gain is equal to (1 + 49.9K/(Rs + Rb)) and the output impedance is very low. As the signal frequency increases beyond fxe, the op amp loses influence and the CLC104 output impedance dominates. To ensure a smooth transition and matched gain at all frequencies, adjust Rs for a minimum op amp output swing with a 0.1Vp-p sine wave input (to the CLC104) at the frequency fxe. Since the CLC104 has a 500Ω output impedance, its output voltage is a function of the load impedance (Av = VR / (Rs + 500)), whereas the gain of the composite amplifier at low frequencies and DC is relatively independent of the load impedance, due to the high open-loop gain of the op amp. Thus, to avoid gain mismatching and phase nonlinearity, use the composite amplifier only if the load impedance is constant from DC to at least 10fV.

Use of a composite amplifier reduces input offset voltage and its corresponding drift, but has no effect on input bias current. This current is converted to an input voltage by the resistance to ground seen at the amplifier input and the voltage appears amplified, at the output. Typical input offset voltage due to the bias current is 2mV and input offset drift is approximately 15µV/°C.

Thermal Considerations

The CLC104 case must be maintained at or below 140°C. Note that because of the amplifier design, power dissipation remains fairly constant, independent of the load or drive level. Therefore, standard derating is not possible. There are two ways to keep the case temperature low. The first is to keep the amount of power dissipated inside the package to a minimum and the second is to get the heat out of the package quickly by reducing the thermal resistance from case to ambient.

A large portion of the heat dissipated inside the package is in the voltage regulators. At the minimum ±9V supply level the regulators dissipate 390mW and at the maximum ±16V supply level they dissipate 1.2W.

The amplifier itself dissipates a fairly constant 600mW (55mW × 10.6V). Reducing the power dissipation of the internal regulators will go far towards reducing the internal junction temperatures without impacting the ac performance. Reducing either the input supply voltages (on pins 1 and 2) and/or shunting the regulator current through external resistors (from pins 1 to 14 and pins 2 to 13) are both effective means towards significantly reducing the internal power dissipation. A minimum voltage across the regulator of 3.6V and a minimum regulator current of 10mA will satisfy the regulator dropout voltage and current limits.

Given the maximum anticipated power supply voltages, the shunt resistor should be calculated to yield a 35mA current from that voltage to the regulated voltage of 5.4V. This will leave 10mA through the regulator at the minimum quiescent current of 45mA. The regulator input voltages may be reduced directly by dropping the voltage supplies, or, if that option is not available, using either a zener or resistive dropping element in series with the supply. If a series dropping element is used, the decoupling capacitors must appear on pins 1 and 2 of the CLC104. Figure 3 shows two possible power reduction circuits from fixed ±15V supplies.

Several methods of decreasing the thermal resistance from case to ambient are possible. With no heat paths other than still air at 25°C, the thermal resistance of case to ambient for the CLC104 is about 40°C/W. When placed in a printed circuit board with all ground pins soldered into a ground plane 1" × 1.5", the thermal resistance drops to about 30°C/W. In this configuration, the case rise will be 30°C for 9V supplies and 50°C for 16V supplies. This results in maximum allowable ambient temperatures of 110°C and 90°C, respectively. If higher operating temperatures are required, heat sinking of the package is recommended.
APPLICATIONS:
- ultra-fast flash A/D conversion
- line driving
- high speed communications
- impedance transformation
- power buffers
- IF processors

DESCRIPTION:
Using a unique closed-loop design, the CLC110 buffer offers a high-fidelity, high-performance alternative to conventional open-loop buffers. For example, the -3dB bandwidth is 730MHz (0.5V_{pp}) and the settling time to 0.2% is typically only 5ns. Yet all this is achieved while maintaining excellent signal fidelity as demonstrated by the -65dBc harmonic distortion at 20MHz—a value unmatched by any high-speed buffer.

The CLC110 is an ideal choice for a wide variety of applications. With its speed and accuracy, the CLC110 offers designers the benefit of buffering signals which might otherwise go unbuffered due to performance penalties imposed by conventional buffers. For example, the CLC110 is well suited for use within closed-loop systems such as amplifier or phase locked loop systems; with its 400ps rise time, its effect on loop dynamics is usually negligible.

Ultra-fast flash A/D converter systems can also benefit from the speed of the CLC110. And, since most flash A/D's have capacitive inputs, the CLC110's dynamic performance has been characterized for various loads. In addition, the amplifier specifications are for a 100Ω load.

The CLC110 is available in several versions to meet a variety of requirements. A three-letter suffix determines the version:

  - -55°C to +125°C

### Notes:

- AC performance is very dependent on layout.
- Specifications apply only in a 50Ω microstrip environment.
- Gain flatness tests are performed from 0.1MHz to 200MHz.

---

**Comlinear reserves the right to change specifications without notice.**
Operation
The CLC110 is based upon a unique, patented closed-loop design, which provides the accuracy characteristics of a closed-loop amplifier, yet also has unmatched dynamic performance.

Printed Circuit Layout and Supply Bypassing
As with any high-frequency device, a good PCB layout is required for optimum performance. This is especially important for a device as fast as the CLC110, which has a typical bandwidth of 730MHz. To minimize capacitive feedthrough, the pins not connected internally (pins 2, 3, 6, and 7) should be connected to the ground plane. Input and output traces should be laid out as transmission lines with the appropriate termination resistors very near the CLC110. On a 0.065 inch epoxy PCB material, a 50Ω transmission line (commonly called stripline) can be constructed by using a trace width of 0.1" over a complete ground plane.

Figure 1 shows recommended power supply bypassing. The ferrite beads are optional and are recommended only where additional isolation is needed from high-frequency (>400MHz) resonances of the power supply.
Parasitic or load capacitance directly on the output of the CLC110 will introduce additional phase shift in the device, which can lead to decreased phase margin and frequency response peaking. A small series resistor before the capacitance effectively decouples this effect. The graphs on the preceding page illustrate the required resistor value and the resulting performance vs. capacitance.
Precision buffered resistors (PRP8351 series from Precision Resistive Products), which have low parasitic reactances, were used to develop the data sheet specifications. Precision carbon composition resistors or standard spirally-trimmed RN55D metal film resistors will work, though they will cause a degradation of AC performance due to their reactive nature at high frequencies.

Evaluation Board
An evaluation board (part number 730012) is available for the CLC110 to assist in the evaluation of the CLC110. It may also be used as a guide in developing a printed circuit layout. Figure 1 shows the board’s schematic; Figures 2 through 4 show the board layout.
Evaluation Board Parts List:
- \( R_{in} \) select for desired input impedance
- \( R_{out} \) select for desired output impedance
- \( C_1, C_2 \) 0.1μF ceramic radial lead
- \( C_3, C_4 \) 6.8μF (Sprague 150D series)
- \( L_1, L_2 \) ferrite beads (optional) (Ferroxcube #VK 200 19/4B)

Application Notes and Assistance
Application notes that address topics such as data conversion, fiber optics, and general high frequency circuit design are available from Comlinear or your Comlinear sales engineer. Comlinear maintains a staff of highly qualified applications engineers to provide technical and design assistance.
APPLICATIONS:
• video crosspoint switch driver
• video distribution buffers
• video switching buffers
• video signal multiplexing
• instrumentation amps
• active filters

DESCRIPTION:
The CLC114 is a high-performance, closed-loop quad buffer intended for power sensitive applications. Requiring only 30mW of quiescent power dissipation per channel (±5V supplies), the CLC114 offers a small signal bandwidth of 200MHz (0.5Vpp) and a slew rate of 450V/μs.

Designed specifically for high density crosspoint switch and analog multiplexer applications, the CLC114 offers excellent linearity and wide channel isolation (62dB @ 10MHz). Driving a typical crosspoint switch load, the CLC114 offers differential gain and phase performance of 0.08% and 0.1%; gain flatness through 30MHz is typically 0.1dB.

With its patented closed-loop topology, the CLC114 has significant performance advantages over conventional open-loop designs. Applications requiring low output impedance and true unity gain stability through very high frequencies (active filters, dynamic load buffering, etc.) will benefit from the CLC114’s superior performance.

Constructed using an advanced, complementary bipolar process and Comlinear’s proven high-speed architectures, the CLC114 is available in several versions to meet a variety of requirements.

CLC114 AJP –40°C to +85°C 14-pin plastic DIP
CLC114 AJE –40°C to +85°C 14-pin plastic SOIC
CLC114 AIB –40°C to +85°C 14-pin hermetic CERDIP
CLC114 A8B –55°C to +125°C 14-pin hermetic CERDIP, MIL-STD-883, Level B

CLC114 ALC –55°C to +125°C dice
CLC114 AMC –55°C to +125°C dice qualified to Method 5008, MIL-STD-883, Level B

Comlinear reserves the right to change specifications without notice.
**Operation**
The CLC114 is a quad, low-power, high-speed, unity-gain buffer. The closed loop topology provides accuracy not found in open loop designs. The input stage incorporates a slew-enhancement circuit which allows low quiescent power without sacrificing ac performance.

**PC Board Layout and Crosstalk**
High frequency devices demand a good printed circuit board layout for optimum performance. The CLC114, with power gain to 200 MHz, is no exception. A ground plane and power supply bypassing with good high-frequency ceramic capacitors in close proximity to the supply pins is essential. Second harmonic distortion can be improved by ensuring equal current return paths for both the positive and the negative supplies. This can be accomplished by grounding the bypass capacitors at the same point in the ground plane while keeping the power supply side of the bypass capacitors within 0.1" of the CLC114 supply pins.

Crosstalk (undesired signal coupling between buffer channels) is strongly dependent on board layout. Closely spaced signal traces on the circuit board will degrade crosstalk due to intertrace capacitance. For this reason it is recommended that unused package pins (2, 4, 6, 11) be connected to the ground plane for better channel isolation at the device pins. Similarly, crosstalk can be improved by using a grounded guard trace between signal traces. This will reduce the distributed capacitance between signal lines.

Following are two graphs depicting the effects of crosstalk. All-hostile crosstalk is measured by driving three of the four buffers simultaneously while observing the fourth, undriven, channel. Figure 2, “All-Hostile Crosstalk Isolation”, shows this effect as a function of input signal frequency. R_L is the resistive load for each driven channel. Figure 3, “Most Susceptible Channel-to-Channel Pulse Coupling”, describes one effect of crosstalk when one channel is driven with a 2Vpp step (tr=5ns) while the output of the undriven channel is measured. From Figure 2 it can be observed that crosstalk decreases as the signal frequency is reduced. Similarly, the pulse coupling crosstalk will decrease as the rise time increases.

**Evaluation Board**
An evaluation board for the CLC114 is available. This board may be ordered as part #730023.

**Unused Buffers**
It is recommended that the inputs of any unused buffers be tied to ground through 50Ω resistors.

**Differential Gain and Phase**
The CLC114 was designed to minimize differential gain and phase errors when driving the distributed capacitance of a video crosspoint switch. Refer to the section “Performance Driving a Crosspoint Switch” for typical values.
APPLICATIONS:
• multi-channel video distribution
• video switching buffers
• high-speed analog multiplexing
• channelized EW
• high-density buffering
• instrumentation amps
• active filters

DESCRIPTION:
The CLC11S is a high performance, closed-loop, quad buffer designed for high density applications requiring a low-cost-per-channel solution to buffering high-frequency signals. The CLC11S's high performance includes a 700MHz small signal bandwidth (0.5Vpp) and a 2700V/μs slew rate while requiring only 11mA quiescent current per channel. Signal fidelity is maintained with low harmonic distortion (~62dBc 2nd and 3rd harmonics at 20MHz), and wide channel separation (60dB crosstalk at 10MHz). Featuring a unique closed-loop design, the CLC11S offers true unity-gain stability and very low output impedance plus a 60mA per channel output drive capability. The CLC11S is ideally suited for buffering video signals with its 0.08%/0.04° differential gain and phase performance at 3.58MHz. Applications such as analog multiplexing and high-speed A/D converters will benefit from the CLC11S's high signal fidelity.

The CLC11S offers a low-cost-per-channel solution to high-speed buffering with four high-performance, closed-loop buffers integrated in one 14-pin package.

FEATURES (typical):
• closed-loop quad buffer
• 700MHz small-signal bandwidth
• 2700V/μs slew rate
• 0.08%/0.04° differential gain/phase
• 60dB channel isolation (10MHz)
• ~62dBc 2nd and 3rd harmonics at 20MHz
• 60mA current output per channel

The CLC115 is available in several versions to meet a variety of requirements:

| Input Capacitance | 1.6 pF | 2.2 pF | 2.2 pF | 2.2 pF | pF | CIN |
| Output Resistance | 1.1 Ω | 4.5 Ω | 2.0 Ω | 2.0 Ω | Ω | RO |
| Output Voltage Range | ±4.0 V | ±3.8 V | ±3.9 V | ±3.9 V | V | VO |
| Output Voltage Range | ±3.7 V | ±3.2 V | ±3.4 V | ±3.0 V | V | VOL |
| Output Current | ±60 mA | ±25 mA | ±48 mA | ±30 mA | mA | IO |

**NOTES:**
- \( V_{cc} \) ±7V
- Al, AJ 100% tested at +25°C, sample at +85°C.
- A8 100% tested at +25°C, −55°C, +125°C.
- Al, AM 100% wafer probed at +25°C to +25°C specifications.

**Specification:**
- Specification is guaranteed for \( 50Ω \leq R_L \leq 200Ω \).

Colinear reserves the right to change specifications without notice.
PC Board Layout and Circuit Design

For optimum performance, high frequency devices demand a good printed circuit board layout. A ground plane and power supply bypassing with good high-frequency ceramic capacitors in close proximity to the supply pins is essential. Second harmonic distortion can be improved by ensuring equal current return paths for both the positive and negative supplies.

The dominant pole, i.e. the high-frequency compensation of the CLC115, is set by the load resistance, $R_L$. Ideally, each buffer of the CLC115 should see a 100Ω load at high frequency to ensure stability. An unterminated channel is undercompensated and will exhibit gain at several hundred megahertz. Signal coupling may occur between channels through the common power supply connections. Any resonance in the power supply can lead to oscillations in the unterminated or undercompensated channel.

In order to compensate and to guarantee the stability of the four CLC115 channels, each must be terminated with a 100Ω resistance to ground. If a dc load is not desired, a two picofarad capacitor can be inserted between the 100Ω load resistor and ground, as shown in Figure 2.

Crosstalk is strongly dependent on board layout. Closely spaced signal traces on the circuit board will degrade crosstalk due to intertrace capacitance. It is recommended that unused package pins (2,4,6,11) be connected to the ground plane for better isolation at the device pins. Similarly, crosstalk can be improved by using a grounded guard-trace between signal lines. This will reduce the distributed capacitance between signal lines.

Two graphs show the effects of crosstalk. All-hostile crosstalk is measured by driving three of the four buffers simultaneously while observing the fourth, undriven channel. Figure 3, "All-Hostile Crosstalk Isolation", shows this effect as a function of input signal frequency. The load for all four channels of the CLC115 is 100Ω. Figure 4, "Most Susceptible Channel-to-Channel Pulse Coupling", describes one effect of crosstalk when one channel is driven with a 4Vpp step (tr=5ns) while the output of the undriven channel is measured. From Figure 3 it can be seen that crosstalk improves as the signal frequency is reduced. Similarly, the pulse coupling crosstalk will improve as the time increases.

Unused Buffers

The output of any unused buffers must be terminated in 100Ω to ground, as discussed above. It is recommended that unused buffer inputs be terminated in 50Ω to ground.

Evaluation Board

An evaluation board for the CLC115 is available. This board may be ordered as part #730023.

</tbody>
</table>

Note 1: Input impedance is dependent upon load impedance and output impedance is dependent upon source impedance. If the external termination impedance at one port varies up or down, the amplifier impedance at the opposite port will likewise change up or down. For example, with \( R_S = 50 \) and \( R_L \propto \), \( R_n = 100 \) and \( R_{out} = 50 \). With \( R_S = R_L = 75, R_n = R_{out} = 65 \) approximately. Gain flatness and other specifications are typically the same in a 75 ohm system as they are in a 50 ohm system.

Note 2: Thermally induced drift will cause post settling drift of 2mV after 200us and 10mV after several seconds.

Maximum ratings:

**CAUTION:** The positive and negative power supplies should come on and go off within one second of each other in order to prevent excessive power dissipation from damaging some internal components. If this requirement cannot be met, the following circuit should be used:

Both \( \pm V_{cc} \) supply voltage inputs are diode clamped to ground to prevent damage to the amplifier in the event that the plus and minus supplies are interchanged. The supply current should be limited to 1 amp maximum in the event.

COMLINEAR CORPORATION

DC TO 250MHz, LINEAR HIGH POWER AMPLIFIER

APPLICATIONS:
• coaxial cable line driver
• baseband and video communications
• pulse amplifiers

FEATURES:
• drives up to 12Vpp into 50 ohm loads
• very low distortion, low offset drift, and low overshoot
• extremely linear phase and wide dynamic range

Connector Options

- CLC 102-BNC
- CLC 102-SMA

Mass: 245 grams

U.S. Patent 4,358,739, 4502020

Comlinear Corporation
Applications:
- IF/HF transceivers
- PMT amplifiers
- coax cable drivers
- signal generator post amps
- general purpose bench-top amps
- video distribution amps

Description:
Comlinear's Modular Series of amplifiers builds on an extensive line of high performance, DC-coupled amplifiers to offer off-the-shelf application specific products. Designed for bench-top or system use, the Modular Series contains a mix of flexible definition and fixed definition amplifiers that provide a broad selection of features.

The fixed definition amplifiers have been optimized for specific applications such as PMT amps and wide dynamic range IF amplifiers, while the flexible definition amplifiers allow a choice of gain and I/O impedances. Packaged in the case styles shown here, these wideband linear amplifiers come ready to use with the addition of bipolar DC power supplies.

Modular Series Fixed Gain Amplifiers
Tuned for optimum performance for a variety of applications, these amplifiers are nominally specified for ±15V power supplies and intended for use in 50Ω matched impedance systems, although some offer optional 75Ω input and/or output impedances. Ordering information requires the identification of one or more of these parameters: either BNC or SMA connector type, input impedance (Zi) and/or output impedance (Zo).

CLC140: Wide Band PMT Amp
Offers excellent high speed pulse response and low noise required of Photo-Multiplier Tube applications.
- DC to 500MHz bandwidth (P0 = 10dBm)
- 0.1dB flatness thru 300MHz
- fixed 20dB non-inverting gain (+10V/V)
- 600ps rise time
- excellent 50Ω I/O VSWR
- low 6dB noise figure
- ±5V to ±15V power supplies
- package type C
- Ordering Information: CLC140-SMA (no BNC)

CLC142: Wide Dynamic Range Power Amp
Combines excellent distortion performance with wide full-power bandwidth.
- DC to 250MHz bandwidth (18dBm)
- fixed 15dB inverting gain (-5.62V/V)
- 50dBm 3rd order intercept (10MHz)
- excellent 50Ω I/O VSWR
- 5000V/µs slew rate
- output short circuit protected
- 27dBm maximum output power
- package type D
- Ordering Information: CLC142-(SMA/BNC)

CLC144: Very Wideband Pulse Amp
Offers the widest band DC-coupled pulse amplifier available from Comlinear.
- DC to 1.1GHz bandwidth (P0 = 12dBm)
- fixed 14dB non-inverting gain (+5V/V)
- <400ps rise times
- 1.2ns overdrive recovery
- excellent phase linearity (1.5° to 750MHz)
- excellent 50Ω I/O VSWR
- package type B
- Ordering Information: CLC144-SMA (no BNC)
CLC146: FET Input Cable Driver
Offers a high input impedance, very low bias current, buffer, with either 50 or 75Ω output impedance, achieving unity gain when driving a matched load.
- DC to 220MHz bandwidth (Pₒ = 10dBm)
- fixed 0dB gain into matched load
- low distortion
- low input noise
- excellent 50Ω or 75Ω output VSWR
- package style A
- Ordering Information: CLC146-(SMA/BNC)-Zₒ

CLC146: Low Distortion, Low Gain Amplifier
Very low harmonic distortion for low gain applications.
- DC to 220MHz bandwidth (Aᵢ = 2, Vᵢ = 2Vpp)
- < -64dBc harmonics (1Vpp, 20MHz, Zₒ = Zᵢ = 50Ω)
- gain range (Aᵢ): +2 to +5
- input impedance (Zᵢ): 50Ω to 1kΩ
- output impedance (Zₒ): 50Ω to 1kΩ
- package type B
- Ordering information: CLC162-(SMA/BNC)-Zᵢ-Zₒ-Aᵢ

Modular Series Flexible Definition Amplifiers
Intended to satisfy user specific applications, these parts offer a broad range of non-inverting gains and I/O impedances with each part emphasizing a particular performance parameter. Overall, these parts cover the +2 to +40 (unterminated output) gain range with 50Ω to 1kΩ I/O impedances. All are intended for ±15V power supplies. Ordering information requires the identification of connector type: either BNC or SMA, input impedance (Zᵢ), output impedance (Zₒ) and the voltage gain (Aᵢ) with an unterminated output. The actual voltage gain to a resistive load, Zᵢ, will be Aᵢ·(Zᵢ/(Zₒ+Zᵢ)).

CLC160: High Power Driver Amp
Offers the highest load power for ±15V supplies with output impedance matching capability.
- DC to 160MHz bandwidth (Aᵢ = 10, Pₒ = 18dBm)
- maximum Pₒ = 24dBm
- gain range (Aᵢ): +5 to +20
- input impedance (Zᵢ): 50Ω to 1kΩ
- output impedance (Zₒ): 50Ω to 200Ω
- output short circuit protected
- package type A
- Ordering information: CLC160-(SMA/BNC)-Zᵢ-Zₒ-Aᵢ

CLC162: Low Distortion, High Gain Amplifier
Offers a high input impedance, buffer, with either BNC or SMA, input impedance (Zᵢ), output impedance (Zₒ) and the voltage gain (Aᵢ) with an unterminated output. The actual voltage gain to a resistive load, Zᵢ, will be Aᵢ·(Zᵢ/(Zₒ+Zᵢ)).

CLC163: Low Distortion, High Gain Amplifier
Very low harmonic distortion for higher gain applications.
- DC to 220MHz bandwidth (Aᵢ = 10, Vᵢ = 2Vpp)
- < -70dBc harmonics (1Vpp, 20MHz, Zᵢ = Zₒ = 50Ω)
- gain range (Aᵢ): +5 to +40
- input impedance (Zᵢ): 50Ω to 1kΩ
- output impedance (Zₒ): 50Ω to 1kΩ
- output short circuit protected
- package type A
- Ordering information: CLC163-(SMA/BNC)-Zᵢ-Zₒ-Aᵢ

CLC166: Low DC Offset, Wideband Amplifier
A general purpose wideband amplifier with lower input offset voltage.
- DC to 150MHz bandwidth (Aᵢ = 20, Vᵢ = 2Vpp)
- less than ±2mV input offset voltage (typ)
- gain range (Aᵢ): +10 to +40
- input impedance (Zᵢ): 50Ω to 200Ω
- output impedance (Zₒ): 50Ω to 1kΩ
- package type B
- Ordering information: CLC166-(SMA/BNC)-Zᵢ-Zₒ-Aᵢ

CLC167: Low DC Offset, High Power Output Amplifier
A wide full power bandwidth amplifier with low input offset voltage.
- DC to 150MHz bandwidth (Aᵢ = 20, Vᵢ = 4Vpp)
- DC to 60MHz bandwidth (Aᵢ = 20, Vᵢ = 20Vpp)
- less than ±2mV input offset voltage (typ)
- gain range (Aᵢ): +10 to +40
- input impedance (Zᵢ): 50Ω to 200Ω
- output impedance (Zₒ): 50Ω to 1kΩ
- package type B
- Ordering information: CLC167-(SMA/BNC)-Zᵢ-Zₒ-Aᵢ

Note 1: The output must not be overdriven for these parts. Therefore the maximum ±Vₒ will be ±(|Vᵢ| - 4V)/Aᵢ.

Comlinear reserves the right to change specifications without notice.
DESCRIPTION:
Comlinear's E Series Amplifiers are designed to take full advantage of Comlinear's high-performance DC-coupled operational and video amplifiers in an easy-to-use, encased form. This format makes the E Series Amplifiers an excellent choice for use on the bench, in a test station, or in other environments needing both high performance and ease of use.

The op amp-based E Series amplifiers (shown in the table below) provide a wide selection of features as well as the ability to customize parameters such as voltage gain and output impedance to the application.

The E104 is an encased version of the CLC104AI, a DC to 1.1GHz linear amplifier with a fixed gain of 14dB and 50.0 input and output impedances. These features, coupled with excellent distortion and VSWR characteristics, make the E104 ideal for applications in wideband analog and high-speed digital communications, radar, and fiber optics transmitters and receivers.

ORDERING INFORMATION:

E104
Since gain and input and output impedances are fixed on the E104, simply designate the connector type required by: E104-BNC or E104-SMA.

E103, E200, E201, E203, E220, E221, and E231
Due to the flexibility possible with these amplifiers, the user must specify several parameters when ordering:

- The full part number is Ennn-p-con-Zi-Zo-Av
  - nnn: specify 103, 200, 201, 203, 220, 221, or 231
  - p: specify N (non-inverting) or I (inverting)
  - con: specify BNC or SMA connectors or NDC for no case
  - Zi: specify input impedance in ohms
  - Zo: specify output impedance in ohms
  - Av: specify voltage gain with output unterminated (ie: Zload = ∞)

Select Zi, Zo, and Av within the following constraints:

<table>
<thead>

</table>

Example: E200-N-BNC-75-50-20 means an E200 with a non-inverting gain, BNC connectors, 75Ω input impedance, 50Ω output impedance, and a voltage gain of 20 volts/volt (unterminated output). (When driving a realistic load, the actual gain is reduced by the factor Zload/(Zi + Zload) due to the resistive divider action of the output impedance, Zo, and the load connected to the amplifier, Zload. The unterminated voltage gain, Av, should be selected with this in mind.)

note 1: nominal configuration

V<sub>cc</sub>: ±15V E103, E104, E200, E201, E220, E221, E231, E203, E204

note 2: When the amplifier is configured with an output impedance (Z<sub>out</sub>) > 0, the maximum output voltage swing (at the load) is reduced by the factor Z<sub>load</sub>/(Z<sub>out</sub> + Z<sub>load</sub>). See the example on the previous page.

note 3: These amplifiers must be kept out of saturation; in other words, the output voltage (determined by V<sub>in</sub> and A<sub>V</sub>) must be kept away from the supply voltage |

note 4: In the non-inverting configuration, the input voltage to the E103 must not exceed ±5V.

DISCUSSION:
The performance specified above is that typically seen for a nominally-configured E Series amplifier; performance for different configurations can be determined using the graphs below. Other parameters not shown can be approximated by referring to the individual hybrid data sheets.

![Relative Bandwidth vs. Gain](image)

At the nominal gain setting of +20 (+2 for the E231), the amplifiers will typically provide 100% of the specified bandwidth; higher gains will reduce the bandwidth somewhat as shown above.

![Relative Bandwidth vs. Load](image)

Listed under the typical specifications table are the nominal loads at which the amplifiers will typically provide 100% of the specified bandwidth. Heavier loads decrease the bandwidth as the plot above indicates. (The total load on the amplifier is the sum of the output impedance, Z<sub>out</sub>, and the load connected external to the amplifier, Z<sub>load</sub>.)

APPLICATIONS:
• infrared system multiplexing
• CCD sensor signals
• radar I/O switching
• high definition video HDTV
• test and calibration

DESCRIPTION:
The CLC532 is a high-speed 2:1 multiplexer with active input and output stages. The CLC532 also employs a closed-loop design which dramatically improves accuracy. This monolithic device is constructed using an advanced high-performance bipolar process.

The CLC532 has been specifically designed to provide settling times of 17ns to 0.01%. This, coupled with the adjustable noise-bandwidth, makes the CLC532 an ideal choice for infrared and CCD imaging systems. Channel-to-channel isolation is better than 80dB @ 10MHz. Low distortion (80dBc) and spurious signal levels make the CLC532 a very suitable choice for both I/O processors and receivers.

The CLC532 is offered over both the industrial and military temperature ranges. The Industrial versions, CLC532AJP/AJE/AID, are specified from -40°C to +85°C and are packaged in 14-pin plastic DIP's, 14-pin SOIC's and 14-pin Side-Brazed packages. The extended temperature versions, CLC532ABB/ABD/ABL-2, are specified from -55°C to +125°C and are packaged in a 14-pin hermetic DIP and 20-terminal LCC packages. (Contact factory for LCC and Cerdip availability.)

Ordering Information ...
CLC532AJP -40°C to +85°C 14-pin plastic DIP
CLC532AJE -40°C to +85°C 14-pin plastic SOIC
CLC532AIB -40°C to +85°C 14-pin Ceradip
CLC532AID -40°C to +85°C 14-pin Side-Brazed
CLC532ABB -55°C to +125°C 14-pin Ceradip; MIL-STD-883
CLC532ABD -55°C to +125°C 14-pin Side-Brazed; MIL-STD-883
CLC532A8L-2A -55°C to +125°C 20-terminal LCC; MIL-STD-883

FEATURES (typical):
• 12-bit settling (0.01%) - 17ns
• low noise - 32µVrms (dc to 100MHz)
• high isolation - 80dB @ 10MHz
• low distortion - 80dBc @ 5MHz
• Adjustable noise bandwidth

#### Conditions
- **Typ**: 3dB bandwidth, gain flatness
- **Min**: 3dB bandwidth, gain flatness
- **Max**: 3dB bandwidth, gain flatness

#### Frequency Domain Performance
- **V_{out}<0.1Vpp**: 190 to 140 to 140 to 110 MHz
- **V_{out}=2Vpp**: 45 to 35 to 35 to 30 MHz
- **peaking**: 0.2 dB to 0.7 dB to 0.7 dB to 0.8 dB
- **roll-off**: 1.0 dB to 1.8 dB to 1.8 dB to 2.6 dB
- **linear phase deviation**: 2.0 deg to 1.8 deg to 1.8 deg to 2.6 deg
- **differential gain**: 0.05 % to 0.01 % to 0.01 % to 0.01 %
- **differential phase**: 0.01 deg to 0.01 deg to 0.01 deg to 0.01 deg
- **crosstalk rejection**: 2Vpp, 10MHz, 75 dB to 75 dB to 75 dB to 74 dB
- **crosstalk rejection**: 2Vpp, 20MHz, 74 dB to 69 dB to 69 dB to 68 dB
- **crosstalk rejection**: 2Vpp, 30MHz, 68 dB to 63 dB to 63 dB to 62 dB

### Time Domain Performance

#### Rise and Fall Time
- **0.5V step**: 2.7 ns to 3.3 ns to 3.3 ns to 3.8 ns
- **2V step**: 10 ns to 12.5 ns to 12.5 ns to 14.5 ns
- **settle time**: 2V step, from 50% V_{out}, 35 ns to 24 ns to 24 ns to 27 ns
- **overshoot**: 2.0V step, 2 ns to 5 ns to 5 ns to 6 ns
- **Slew Rate**: 160 V/μs to 130 V/μs to 130 V/μs to 110 V/μs

### Switch Performance
- **50% SELECT to 10%V_{out}**: 5 ns to 7 ns to 7 ns to 8 ns
- **50% SELECT to 90%V_{out}**: 15 ns to 20 ns to 20 ns to 23 ns

### Distortion and Noise Performance
- **2nd harmonic distortion**: 2Vpp, 5MHz, 80 dBc to 67 dBc to 67 dBc to 67 dBc
- **3rd harmonic distortion**: 2Vpp, 5MHz, 86 dBc to 68 dBc to 68 dBc to 68 dBc
- **Equivalent Input Noise**: 3 nV/Hz to 1 μV/Hz to 1 μV/Hz to 1 μV/Hz
- **Integrated Noise**: 32 μVrms to 42 μVrms to 42 μVrms to 46 μVrms

### Static and DC Performance
- **Analog Output Offset Voltage**: 1 mV to 6.5 mV to 3.5 mV to 5.5 mV
- **Temperature Coefficient**: 15 μV/°C to 90 μV/°C to 20 μV/°C
- **Analog Input Bias Current**: 50 μA to 250 μA to 120 μA to 120 μA
- **Temperature Coefficient**: 0.3 μA to 2.0 μA to 0.8 μA to 0.8 μA
- **Analog Input Bias Current Matching**: 200 μA to 90 μA to 120 μA to 120 μA
- **Analog Input Capacitance**: 2 pF to 3.0 pF to 2.5 pF to 2.5 pF
- **Gain Accuracy**: ±2V, 0.998 to 0.975 to 0.975 to 0.975
- **Gain Matching**: ±2V, TBD to TBD to TBD to TBD
- **Integral Endpoint Non-Linearity**: ±1V (full scale), 0.02 μV/°C to 0.05 μV/°C to 0.03 μV/°C to 0.03 μV/°C
- **Output Voltage**: ±3.4 V to 2.4 V to 2.8 V to 2.8 V
- **Output Current**: ±50 mA to 30 mA to 30 mA to 30 mA
- **Output Resistance**: ±1V, no load, 1.5 Ω to 4.0 Ω to 2.5 Ω to 2.5 Ω

### Digital Input Performance
- **ECL Mode (pin 6 floating)**
  - **Input Voltage Logic HIGH**: -1.1 V to -1.1 V to -1.1 V to -1.1 V
  - **Input Voltage Logic LOW**: -1.5 V to -1.5 V to -1.5 V to -1.5 V
  - **Input Current Logic HIGH**: 14 mA to 50 mA to 30 mA to 30 mA
  - **Input Current Logic LOW**: 50 mA to 270 mA to 110 mA to 110 mA
- **TTL Mode (pin 6 = 5V)**
  - **Input Voltage Logic HIGH**: 2.0 V to 2.0 V to 2.0 V to 2.0 V
  - **Input Voltage Logic LOW**: 0.8 V to 0.8 V to 0.8 V to 0.8 V
  - **Input Current Logic HIGH**: 14 mA to 50 mA to 30 mA to 30 mA
  - **Input Current Logic LOW**: 50 mA to 270 mA to 110 mA to 110 mA

### Power Requirements
- **Supply Current**: ±5.0V, no load, 23 mA to 30 mA to 28 mA to 25 mA
- **Supply Current**: ±5.2V, no load, 24 mA to 31 mA to 30 mA to 26 mA
- **Nominal Power Dissipation**: no load, 240 mA to 240 mA to 240 mA to 240 mA
- **Power Supply Rejection Ratio**: ±5.0V, 73 dB to 60 dB to 64 dB to 64 dB

Operation

The ClC532 is a 2:1 analog multiplexer with high-impedance buffered inputs, and a low-impedance, low-distortion, output stage. The ClC532 employs a closed-loop design, which dramatically improves accuracy. The channel SELECT control (Figure 1) determines which of the two inputs (IN_A or IN_B) is present at the OUTPUT. Beyond the basic multiplexer function, the ClC532 offers compatibility with either TTL or ECL logic families, as well as adjustable bandwidth.

Digital Interface and Channel SELECT

The ClC532 functions with ECL, TTL and CMOS logic families. DREF controls logic compatibility. In normal operation, DREF is left floating, and the channel SELECT responds to ECL level signals, Figure 2. For TTL or CMOS level SELECT inputs (Figure 3), DREF should be tied to +5V (the ClC532 incorporates an internal 2300Ω series isolation resistor for the DREF input). For TTL or CMOS operation, the channel SELECT requires a resistor input network to prevent saturation of the channel select circuitry. Without this input network, channel SELECT logic levels above 3V will cause internal junction saturation and slow switching speeds.

Compensation

The ClC532 incorporates compensation nodes that allow both its bandwidth and its settling time/slew rate to be adjusted. Bandwidth and settling time/slew adjustments are linked, meaning that lowering the bandwidth also lowers slew rate and lengthens settling time. Proper adjustment (compensation) is necessary to optimize system performance. Time Domain applications should generally be optimized for lowest RMS noise at the ClC532 output, while maintaining settling time and slew rates at adequate levels to meet system needs. Frequency Domain applications should generally be optimized for maximally flat frequency response.

Figure 4 below describes the basic relationship between bandwidth and Rs for various values of load capacitance, C_L, where C_COMP = 10pF.

\[
\text{OUTPUT NOISE}_{\text{RMS}} = (n_v)(\sqrt{1.57 \times \text{BW}_{3\text{dB}}})
\]

where... \( n_v \) = input spot noise voltage; \( \text{BW}_{3\text{dB}} \) = Bandwidth is from figure 5.
Power Supplies and Grounding
Proper power supply bypassing and grounding is essential to the CLC532's operation. A 0.1μF to 0.01mF ceramic chip capacitor should be located as close as possible to the individual power supply pins. Larger +6.8μF tantalum capacitors should be used within a few inches of the CLC532. The ground connections for these larger by-pass capacitors should be very symmetrically located relative the CLC532 output load ground connection. Harmonic distortion can be heavily influenced by non-symmetric decoupling capacitor grounding. The smaller chip capacitors located directly at the power supply pins are not particularly susceptible to this effect.

Separation of analog and digital ground planes is not recommended. In most cases, a single low-impedance ground plane will provide the best performance. In those special cases requiring separate ground planes, the following table indicates the signal and supply ground connections.

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

Input Shielding
The CLC532 has been designed for use in high-speed wide-bandwidth systems. Guard-ring traces and the use of the ground pins separating the analog inputs are recommended to maintain high isolation (Figure 6). Likely sources of noise and interference that may couple onto the inputs, are the logic signals and power supplies to the CLC532. Other types of clock and signal traces should not be overlooked, however.

![Figure 6: Alternate Layout Using Guard Ring](image)

The general rule in maintaining isolation has two facets, minimize the primary return ground current path impedances back to the respective signal sources, while maximizing the impedance associated with common or secondary ground current return paths. Success or failure to optimize input signal isolation can be measured directly as the isolation between the input channels with the CLC532 removed from circuit. The channel-to-channel isolation of the CLC532 can never be better than the isolation level present at its inputs.

Special attention must be paid to input termination resistors. Minimizing the return current path that is common to both of the input termination resistors is essential. In the event that a ground return current from one input termination resistor is able to find a secondary path back to its signal source (which also happens to be common with either the primary or secondary return path for the second input termination resistor), a small voltage can appear across the second input termination resistor. The small voltage seen across the second input termination resistor will be highly correlated with the signal generating the initial return currents. This situation will severely degrade channel-to-channel isolation at the input of the CLC532, even if the CLC532 were removed from circuit. Poor isolation at the input will be transmitted directly to the output.

Use of "small" value input termination resistors will also improve channel-to-channel isolation. However, extremely low values (<25Ω) tend to stress the driving source's ability to provide a high-quality input signal to the CLC532. Higher values tend to aggravate any layout dependent crosstalk. 75Ω to 50Ω is a reasonable target, but the lower the better.

Combining Two Signals in ADC Applications
The CLC532 is applicable in a wide range of circuits and applications. A classic example of this flexibility is combining two or more signals for digitization by an analog-to-digital converter (ADC). A clear understanding of both the multiplexer and the ADC's operation is needed to optimize this configuration.

To obtain the best performance from the combination, the output of the CLC532 must be an accurate representation of the selected input during the ADC conversion cycle. The time at which the ADC samples the input varies with the type of ADC that is being used.

Subranging ADCs usually have a Track-and-Hold (T/H) at their input. For a successful combination of the multiplexer and the ADC, the multiplexer timing and the T/H timing must be compatible. When the ADC is given a convert command, the T/H transitions from Track mode to Hold mode. The delay between the convert command and this transition is usually specified as Aperture Delay or as Sampling Time Offset.

To maximize the time that the multiplexer output has to settle, and that the T/H has to acquire the signal, the multiplexer should begin its transition from one input to the other immediately after the T/H transition into HOLD mode. Unfortunately it is during the initial portion of the HOLD period that a subranging ADC performs analog processing of the sampled signal. High slew rate transitions on the input during this time may have a detrimental effect on the conversion accuracy.

To minimize the effects of high input slew rates, two strategies that can employed. Strategy one applies when the sample rate of the system is below the rated speed of the ADC. Here the CLC532 SELECT timing is delayed until after the multiplexer transition takes place, and after the A/D has completed one conversion cycle and is waiting for the next convert command. As an example, if a CLC935 (15MSPS) ADC is being used at 10MSPS, the conversion takes place in the first 67ns after the CONVERT command. The next 33ns are spent waiting for the next CONVERT command, and would be an ideal place to switch the multiplexer from one channel to the next.

![Figure 7: Recommended Ccomp vs. ADC Sample Rate](image)

The second optimization strategy involves lowering the slew rate at the input of the ADC so that fewer high frequency components are available to feed through to the hold capacitor during HOLD
mode. The CLC532 output signal can be slew limited by using its compensation capacitors. This approach also has the advantage of limiting the excess noise passed through the CLC532 and on to the ADC. Figure 7 shows the recommended $C_{\text{COMP}}$ values as a function of ADC Sample rate. Since the optimal values will change from one ADC to the next, this graph should be used as a starting point for $C_{\text{COMP}}$ selection. Both $C_{\text{COMP}}$ capacitors should be the same value to maintain output symmetry.

Flash ADCs are similar to subranging ADCs in that the sampling period is very brief. The primary difference is that the acquisition time of a flash converter is much shorter than that of a subranging ADC. With a flash ADC, the transition of the CLC532 output should be after the sampling instant ("Aperture Delay" after the CONVERT command). It is only during this period that a flash converter is susceptible to interference from a rapidly changing analog input signal.

Gain Selection for an ADC
In many applications, such as RADAR, the dynamic range requirements may exceed the accuracy requirements. Since wide dynamic range ADCs are also typically highly accurate ADCs, this often leads the designer into selecting an ADC which is a technical overkill and a budget buster. By using the CLC532 as a selectable-gain stage, a less expensive ADC can be used. As an example, if an application calls for 80dB of dynamic Range and 0.05% accuracy, rather than using a 14-bit converter, a 12-bit converter combined with the circuit in figure 8 will meet the same objective. The CLC532 is used to select between the analog input signal and a version of the input signal attenuated by 12dB. This circuit affords 14-bit dynamic range, 12-bit accuracy and 12-bit ease of implementation.

Figure 8: Selectable Gain Stage Improves ADC Dynamic Range

Full Wave Rectifier Circuit
The use of a diode rectifier provides significant distortion for signals that are small compared to the forward bias voltage. Accordingly, when low distortion performance is needed, standard diode based circuits do not work well. The CLC532 can be configured to provide a very low distortion full wave rectifier. The circuit in figure 9 is used to select between an analog input signal and an inverted version of the input signal. The resulting output exhibits very little distortion for small scale signals up to several hundred kilohertz.

Figure 9: Low Distortion Full Wave Rectifier

Use of the CLC532 as a Mixer.
A double balanced mixer, such as is shown in figure 10, operates by multiplying the RF input by the LO input. This is done by using the LO to select one of two paths through a diode bridge depending upon the LO sign. The result is an output where $\text{IF}=\text{RF}$ when $\text{LO}>0$ and $\text{IF}=\text{-RF}$ if $\text{LO}<0$. This same result can be obtained with the circuit shown in figure 11. The CLC532 based circuit uses a digital LO making system design easier in those cases where the LO is digitally derived. One advantage of the CLC532 based approach is excellent isolation between all three ports. Also see the RF design awards article by Thomas Hack in the January 1993 issue of RF Design.

Figure 10: Typical Double-Balanced Mixer

Figure 11: High-Isolation Mixer Implementation

Evaluation Board
An evaluation board (part number 730028) for the CLC532 is available. This board is used for fast, trouble-free, evaluation and characterization of the CLC532. Additionally, this board serves as a template for layout and fabrication information. The CLC532 evaluation board data sheet is available from Comlinear.
APPLICATIONS:
- infrared system multiplexing
- CCD sensor signals
- radar I/Q switching
- high definition video HDTV
- test and calibration

DESCRIPTION:
The CLC533 is a high-speed 4:1 multiplexer employing active input and output stages. The CLC533 also employs a closed-loop design which dramatically improves accuracy over conventional analog multiplexer circuits. This monolithic device is constructed using an advanced high-performance bipolar process.

The CLC533 has been specifically designed to provide a 24ns settling time to 0.01%. This coupled with the adjustable bandwidth, makes the CLC533 an ideal choice for infrared and CCD imaging systems, with channel-to-channel isolation of 80dB @ 10MHz. Low distortion and spurious signal levels (-80dBc) make the CLC533 a very suitable choice for I/O processors in Radar receivers.

The CLC533 is offered over both the industrial and military temperature ranges. The Industrial versions, CLC533AJP/AJE/AIB, are specified from -40°C to +85°C and are packaged in 16-pin plastic DIPs, SOIC's and CERDIP packages. The extended temperature versions, CLC533A8/A8L-2A, are specified from -55°C to +125°C and are packaged in 16-pin CERDIP and 20-terminal LCC packages.

Ordering Information ...
CLC533AJP -40°C to +85°C 16-pin plastic DIP
CLC533AJE -40°C to +85°C 16-pin plastic SOIC
CLC533A8B -40°C to +85°C 16-pin CERDIP
CLC533A8B -55°C to +125°C 16-pin CERDIP, MIL-STD-883
CLC533A8L-2A -55°C to +125°C 20-terminal LCC, MIL-STD-883

FEATURES (typical):
- 12-bit settling (0.01%) - 17ns
- low noise - 42μVRms (dc to 100MHz)
- isolation - 80dB @ 10MHz
- low distortion - 80dB @ 5MHz
- adjustable bandwidth

OPERATION
The CLC533 is a 4:1 analog multiplexer with high-impedance buffered inputs, and a low-impedance, low-distortion, output stage. The CLC533 employs a closed-loop design, which dramatically improves accuracy. The channel select controls (A and A') determine which of the four inputs (IN thru IN) is present at the OUTPUT. Beyond the basic multiplexer function, the CLC533 offers compatibility with either TTL/CMOS or ECL logic families, as well as adjustable bandwidth.

Digital Interface and Channel SELECT
The CLC533 functions with ECL, TTL and CMOS logic families. D_REF controls logic compatibility. In normal operation, D_REF is left floating, and the channel select controls (A and A') respond to ECL level signals, Figure 1. For TTL or CMOS level SELECT inputs (Figure 2), D_REF should be tied to +5V (the CLC533 incorporates an internal 2300Ω series isolation resistor for the D_REF input).

![Figure 1: ECL Level Channel SELECT Configuration](image)

![Figure 2: TTL/CMOS Level Channel SELECT Configuration](image)

Power Supplies and Grounding
Proper power supply bypassing and grounding is essential to the CLC533’s operation. A 0.1μf to 0.01μf ceramic chip capacitor should be located as close as possible to the individual power supply pins. Larger +6.8μf tantalum capacitors should be used in the immediate area of the CLC533. The ground connections for these larger by-pass capacitors should be very symmetrically located relative the CLC533 output load ground connection. Harmonic distortion can be heavily influenced by non-symmetric decoupling capacitor grounding. The smaller chip capacitors located directly at the power supply pins are not particularly susceptible to this effect.

Separation of analog and digital ground planes is not recommended. In most cases, a single low-impedance ground plane will provide the best performance.

Input Shielding
The CLC533 has been designed for use in high-speed wide-dynamic range systems. Guard-ring traces and the use of the ground pins separating the analog inputs is required to maintain high isolation (Figure 3). Likely sources of noise and interference that may couple onto the inputs, are the logic signals and power supplies to the CLC533. Other types of clock and signal traces should not be overlooked, however.

![Figure 3: Analog Input Using Guard Ring](image)

The general rule in maintaining isolation has two facets, minimize the primary return ground current path impedances back to the respective signal sources, while maximizing the impedance associated with common or secondary ground current return paths. Success or failure to optimize input signal isolation can be measured directly as the isolation between the input channels with the CLC533 removed from circuit. The channel-to-channel isolation of the CLC533 can never be better than the isolation level present at its inputs.

Special attention must be paid to input termination resistors. Minimizing the return current path that is common to both of the input termination resistors is essential. In the event that ground return current from one input termination resistor is able find a secondary path back to its signal source (which also happens to be common with either the primary or secondary return path for the second input termination resistor), a small voltage will appear at the second input which is completely dependent on the first input signal. This situation will severely degrade channel-to-channel isolation at the input of the CLC533, even if the CLC533 were removed from circuit. Poor isolation at the input will be transmitted directly to the output.

Use of "small" value input termination resistors will also improve channel-to-channel isolation. Extremely low values, <25Ω, tend to stress the driving source’s ability to provide a high-quality input signal to the CLC533. Higher values tend to aggravate any layout dependent crosstalk. 75Ω to 50Ω is a reasonable target, but the lower the better.

Evaluation Board
An evaluation board (part number 730035 for DIP’s and 730039 for SOIC’s) for the CLC533 is available. This board can be used for fast, trouble-free, evaluation and characterization of the CLC533. Additionally, this board serves as a template for layout and fabrication information. The CLC533 evaluation board data sheet is available from Comlinear.

APPLICATIONS:
- flash A/D driving
- high-resolution, subranging A/D driving
- signal deglitching (as in CCD or D/A systems)
- communication systems
- radar and IF processors

DESCRIPTION
The CLC940 Flash-Track™ is a fast sampling, wideband track and hold amplifier which offers 12ns switching performance plus an unprecedented array of supporting specifications. This combination ensures that the accuracy indicated by the switching specifications is fully realized.

The Flash-Track is an ideal device for driving flash A/Ds—especially those configured in high resolution, subranging architectures. The very fast 10ns hold-to-track acquisition time and 12ns track-to-hold settling time permit the high sampling rates needed in applications such as radar and communications. Other specifications, such as the 1ps aperture jitter, 2mV pedestal offset, and -57dB harmonic distortion are similarly supportive of A/D system performance goals. The CLC940 is fully compatible with demanding flash A/D input requirements as demonstrated by its ±2.2V output range and its ability to drive up to 90pF loads at full performance.

Ease of use and functionality are also characteristics of the Flash-Track; for example, the device needs only ±15V supplies and can accept either ECL or TTL control signals. In addition, conservative specifications and 100% testing assure dependable, consistent insystem performance.

The CLC940 is constructed using thin film resistor/bipolar transistor technology. The CLC940AI is specified over a temperature range of -25°C to +85°C, while the CLC940AM is specified over a range of -55°C to +125°C and is screened to Comlinear’s M Standard for high reliability applications. Both devices are packaged in 24-pin, 800 mil wide, ceramic DIPs.

FEATURES (typical):
- 10ns hold-to-track acquisition time
- 12ns track-to-hold settling time
- 1ps aperture jitter
- 150MHz small signal bandwidth
- 74dB feedthrough rejection
- ECL or TTL control signals

- 3rd harmonic distortion: 2Vpp, 20MHz, \(R_L = 1k\Omega\) < 60 < 54 < 54 < 60 dBc

#### HOLD-MODE DYNAMICS

- droop rate: 20 < 250 < 50 < 2000 μV/μs
- feedthrough rejection: 74 > 70 > 70 > 70 dB

#### TRACK-TO-HOLD SWITCHING

- effective aperture delay: 2.5 < 3.3 < 3.0 < 3.0 ns
- aperture jitter: 1 < 1.4 < 1.4 < 1.6 ps rms
- pedestal offset: 2 < 8 < 5 < 8 mV
- sensitivity to supply voltage: 25 < 60 < 60 < 60 μV/°C
- switching transient (peak-to-peak amplitude) \(t_s = 2MHz\): 25 < 50 < 30 < 40 mVpp
- track-to-hold settling time: 12 < 18 < 14 < 14 ns

#### HOLD-TO-TRACK SWITCHING

- acquisition time to 1.0%: 10 < 15 < 12 < 12 ns
- to 0.1%: 16 < 22 < 18 < 22 ns

#### DC ACCURACY

- gain: 1kHz, 4Vpp, no load: 0.98 < 0.96 < 0.96 < 0.96 V/V
- temperature coefficient: 20 < 30 < 30 < 30 ppm/°C
- non-linearity: 0.02 < 0.025 < 0.025 < 0.025 %
- offset voltage: 20 < 75 < 60 < 60 mV
- temperature coefficient: 30 < 140 < 140 < 140 μV/°C
- power supply rejection ratio: 40 < 36 < 36 < 36 dB

#### DIGITAL INPUTS

- differential input threshold: \(|V_{\text{track}} - V_{\text{hold}}|\) — < 300 < 300 < 300 mV
- input bias current (track mode): 25 < 100 < 50 < 50 μA
- input bias current (hold mode): 1 < 10 < 5 < 5 μA

#### ANALOG INPUT

- input voltage range: — ± 2.2 ± 2.2 ± 2.2 V
- input resistance: 20 > 15 > 15 > 15 kΩ
- input capacitance: 3 < 4 < 4 < 4 pF
- input bias current: 30 < 90 < 60 < 60 μA

#### ANALOG OUTPUT

- output resistance: at 1kHz — 10 < 12 < 12 < 12 Ω

#### POWER REQUIREMENTS

- supply current: \(V_{in} = 0\), track mode, no load: 55 < 65 < 60 < 60 mA
- power dissipation: \(V_{in} = 0\), track mode, no load: 1.65 < 1.95 < 1.80 < 1.80 W

### Note

- **Note 1:** Parameters preceded by an * are the final electrical test parameters and are 100% tested. AM units are tested at -25°C, +25°C, and +125°C. AM units are tested only at +25°C although their performance is guaranteed at -25°C and +85°C as indicated above.
- **Note 2:** For optimum performance the differential voltage between the input and output should not exceed 3V in HOLD mode.
- **Note 3:** Absolute Maximum Ratings are limiting values, to be applied individually, and beyond which the serviceability of the circuit may be impaired. Functional operation under any of these conditions is not necessarily implied. Exposure to absolute maximum ratings for extended periods may affect device reliability.

Comlinear reserves the right to change specifications without notice.

9 – 4
**Thermal Model Calculations**

- **P_Cir** = \( I_{cc1} [V_{cc1} - (-V_{cc1})] + I_{cc2} [V_{cc2} - (-V_{cc2})] \)
  \( I_{cc1} \) is the supply current to \( \pm V_{cc1} \) (pins 22 and 3).
  \( I_{cc2} \) is the supply current to \( \pm V_{cc2} \) (pins 17 and 12).
- Typical values are \( \pm V_{cc1} = \pm 15V \), \( I_{cc1} = 34mA \), \( \pm V_{cc2} = \pm 12V \), \( I_{cc2} = 15mA \).
- So \( P_{Cir} = (34mA)(30V) + (15mA)(24V) = 1.38W \)

- **P_{XXX}** = \( \pm V_{ee} - V_{out} \\ - I_{col} (R_{col} + 10) \) \( I_{col} \) (duty cycle that XXX is on)
  \( P_{XXX} \) is the power in either the npn or pnp output transistor.
  For \( V_{out} > 0 \), the power is in the npn and \( \pm V_{ee} = +V_{ee} \).
  For \( V_{out} < 0 \), the power is in the pnp and \( \pm V_{ee} = -V_{ee} \).
  \( I_{col} = V_{out}/R_{load} \) or 4mA whichever is greater.
  \( R_{col} \) is the external resistor between the XXX collector and \( \pm V_{ee} \).

- **Example:** \( V_{out} = +1V \), 30% duty cycle
  \( V_{out} = -2V \), 70% duty cycle
  \( R_{col} = 33\Omega, R_{load} = 1000\Omega \)

  - **P_{npn}** = \( \left[ 15V - 1V - \left( -\frac{1V}{1000} \right) \right] \left( \frac{33\Omega + 10\Omega}{1000} \right) \left( \frac{1V}{1000} \right) \left( 30\% \right) = 0.041W \)

  - **P_{pnp}** = \( \left[ -15V - (-2V) - \left( -\frac{2V}{1000} \right) \right] \left( \frac{33\Omega + 10\Omega}{1000} \right) \left( -\frac{2V}{1000} \right) \left( 70\% \right) = 0.170W \)

- **\( T_{case} \)** = \( P_{total} \theta_{ca} + T_{ambient} = (P_{Cir} + P_{npn} + P_{pnp}) \theta_{ca} + T_{ambient} \)
- **\( T_{Cir} = P_{Cir} (16^\circ C/W) + T_{case} \)**
- **\( T_{npn} = P_{npn} (200^\circ C/W) + T_{case} \)**
- **\( T_{pnp} = P_{pnp} (150^\circ C/W) + T_{case} \)**

\( \theta_{ca} = 23^\circ C/W \) in still air without a heat sink. (With heating sink or air flow, \( \theta_{ca} \) will be lower.)
Track/Hold Switching Control

The switch in the CLC940 is controlled by a pair of differential inputs. The device will be in track mode when the voltage on "track," pin 2, is greater than the voltage on "hold," pin 1. Similarly, it will be in hold mode when the voltage on "hold" is greater than that on "track." The best switching action is realized when the slew rate of the digital input is at least 20V/μs and when the differential signal excursion is no less than 300mV. In addition, it is recommended that the differential voltage on these pins not exceed ± 2.5V while the absolute voltage on either pin should not exceed (∣Vout∣−11V). This voltage range accommodates most logic families.

Differential ECL signals may be fed directly to the digital control inputs, each of which represents less than one ECL 10k load. In Figure 2 below, the CLC940 is in track mode when the non-inverting ECL output is high.

A single-ended ECL signal can be fed directly into one of the digital inputs while the other pin is biased at −1.4V to accommodate ECL voltage levels. In Figure 3 below, the CLC940 is in track mode when the ECL output is high.

For totem-pole-output TTL, a similar connection scheme is used but with a bias voltage of +1.4V. The digital input represents about 5 LSTTL loads at a high level. In Figure 4 below, the CLC940 is in track mode when the TTL output is high.

Driving Capacitive Loads

In order to maintain performance while driving capacitive loads, a small-value resistor should be placed between the CLC940 output and the load. The optimum value of resistance should be selected from the plot of Rout versus Load Capacitance. (See the plot page) For this combination, acquisition time is shown on the Acquisition Time versus Load Capacitance plot. (If the load capacitance is variable, as in some flash A/Ds, the average typical capacitance should be used.)

Layout Considerations

For optimum performance from any precision high-speed track and hold, such as the CLC940, a good printed circuit board layout is necessary. First, provide a ground return path for signal current loops. One such loop is formed between the signal source and the termination resistor at the analog input of the track and hold. Another is formed between the source of the digital sample command and the termination resistors at the digital inputs of the track and hold. In the third such loop, current from the power supplies flows through the track and hold output amplifier to the load and then through the ground return and supply decoupling capacitors to the power supply. Ideally, the input, output, and digital input signals should be transmitted via properly-terminated controlled-impedance transmission lines, such as microstrip or stripline, which work very well on standard printed circuit boards. When a capacitive or high-impedance load makes transmission lines unattractive, just be sure to keep the load within an inch or two of the CLC940 output and provide a wide strip of ground plane for the signal current to return to the decoupling capacitors.

Second, be sure that the ground return paths mentioned above do not cross with themselves or any other ground return on your printed circuit board. Otherwise, signals will be coupled and they will degrade the track and hold precision. For example, to maintain the feedthrough rejection specification, the ground connections of the decoupling capacitors should be kept at least 0.25" away from the signal terminations (such as the ground side of Rin).

Third, keep the stray reactance of the decoupling capacitors and termination resistors low. Use surface-mounted multilayer 0.01μF capacitors right at the power supply pins of the CLC940 if possible. If radial lead capacitors are used, be sure that low-loss types with very short leads are used.

Sockets are not recommended, though some low-profile, "bucket"-type sockets work well (see the parts list in Figure 5). Wire wrap methods and boards should not be used. To assist the designer in evaluating the CLC940, an evaluation board is available at minimal cost.

Figure 1: recommended circuit

Figure 2: differential ECL control

Figure 3: single-ended ECL control

Figure 4: TTL control
Acquisition Time (hold to track) is the time required for the track and hold to acquire the input signal to a specific settling precision when it switches from hold mode to track mode. It is the time from the point when the output starts changing to the point when the output has settled.

Analog Delay (input to output) is the time required for a signal to travel from the analog input to the analog output. Typically, it is 3ns for the CLC940.

Aperture Jitter or aperture uncertainty is the sample-to-sample variability in Effective Aperture Delay which is caused by a small amount of noise in the switch control circuitry. Aperture Jitter changes the time at which the device goes into hold mode. Coupled with the rate of change (slew rate) of the signal at the storage capacitor, Aperture Jitter causes an error in the held output voltage. (Output voltage error = ΔV/Δt * Δt, where ΔV/Δt is the slew rate and Δt is the Aperture Jitter.)

Droop Rate is a drift in the held output voltage. It is caused by leakage currents flowing into (or out of) the storage capacitor from the switching circuit and the input stage of the output amplifier.

Effective Aperture Delay tells when the input signal is actually being sampled. It takes into account two delays: 1) the input signal transit time through the input amplifier and 2) the time needed for the switch to open after the part is given the hold command. Typically, the Effective Aperture Delay is 2.5ns which means the held voltage is that which was at the input 2.5ns after the hold command was given. (Conceivably, Effective Aperture Delay could be negative if the transit time through the input amplifier were longer than the delay in the switch, though this is not the case with the CLC940.)

Feedthrough Rejection or analog input isolation describes how well the switch keeps the input signals from "feeding through" to the output when the device is in hold mode. It is the ratio of the signal that passes through the open switch to the signal at the analog input. Since signal feedthrough is, in part, caused by the capacitance of the switch, Feedthrough Rejection is better for low-frequency input signals (see the plot page for the Feedthrough Rejection vs. Frequency plot). There are, of course, switching transients which feed through from the digital inputs; however, these settle out quickly and are accounted for in the Acquisition Time and Track-to-Hold Settling Time specifications.

Hold-to-Track Switch Delay is the time delay from the track command to the point when the output voltage begins to change as it starts to acquire the new signal. Typically, it is 6ns for the CLC940.

Pedestal Offset or track-to-hold offset is an output offset voltage found in hold mode. (See the Switching Transients and Pedestal Offset on the plot page.) It is caused by a small amount of charge injected into (or out of) the storage capacitor when the (diode bridge) switch opens. In practice, this offset is treated just as an output offset voltage. Unlike the Pedestal Offsets of many other high-speed track and holds, the CLC940’s Pedestal Offset is virtually unaffected by changes in the analog input voltage.

Track-to-Hold Switching Transient is the switch-induced transient voltage which appears at the output immediately after the device switches from track to hold. (See Track-to-Hold Settling Time and the Switching Transients and Pedestal Offset on the plot page.)

Track-to-Hold Settling Time is the time required for the Track-to-Hold Switching Transient to settle out to the point where the output is within 1mV of its final value. (See Track-to-Hold Switching Transient and the Switching Transients and Pedestal Offset on the plot page.)
Lower Power Operation

The power dissipation in the output stage transistors may be decreased by reducing the output-stage supply voltages, ±Vee, to as low as ±5V. This only minimally affects performance, yet can substantially reduce output transistor junction temperatures (see the thermal model).

CLC940 Evaluation Board

An evaluation board (part number 730011) is available for the CLC940. The board is user-configurable for either TTL or ECL operation. (See Figure 5) On the board near pin 1 of the CLC940 are four points labeled “A”, “H”, “B”, and “T.” (See Figure 5 and Figure 6.) Jumpers are connected between these points to provide the CLC940 with the bias voltages needed for single-ended ECL and TTL. Points “H” and “T” go to the “hold” and “track” inputs, respectively. Point “A” goes to the “digital input,” and “B” goes to the TTL/ECL bias network.

The connection scheme for TTL requires that the bias network provide +1.4V at point “B.” The +15V supply is used and the diodes are inserted so as to be forward biased. (See Figures 4 and 5.) Jumpers are used to connect “A” to “H” and “B” to “T.”

Single-ended ECL is connected similarly, however the bias network should be configured to provide −1.4V at point “B.” The −15V supply is used and the diodes are inserted so as to be forward biased. (See Figures 3 and 5.) Jumpers are used to connect “A” to “H” and “B” to “T.”

For differential ECL, signals can be sent directly to points “H” and “T,” the “hold” and “track” inputs respectively. The bias circuit and jumper connections should be omitted. (See Figures 2 and 5.)

The resistor at the digital input, R0, is omitted for TTL and ECL, but is otherwise used to set the (digital) input impedance. The resistor at the analog input, RAN, is selected for the desired input impedance. The output resistor, Rout, is selected for the desired output impedance and for optimum capacitive-load performance. (See the Rout vs Load Capacitance plot on the plot page.)

For TTL, use the bias circuit shown. Omit R0.

For single-ended ECL, reverse the direction of the diodes and connect R0 to −15V instead of +15V. Omit R0.

For differential ECL, omit the jumper connections “A” to “H” and “B” to “T.” Omit bias circuit.

Make connections directly to “H” and “T.”...
APPLICATIONS:
• flash A/D driver
• high-resolution, subranging A/D driver
• signal deglitching (as in CCD or D/A systems)
• communication systems
• radar and IF processors

DESCRIPTION:
The CLC942 is a 12-Bit accurate, fast sampling, wideband track-and-hold amplifier which offers 5ns switching performance. Closed-loop monolithic buffers ensure that switching accuracy is fully realized. The CLC942 is an improved alternate source for the HTS-0010 and the SHC600.

The CLC942 is an ideal device for driving flash A/D's, especially those configured in high resolution, subranging architectures. The 25ns hold-to-track acquisition time (0.01%) and very fast 5ns track-to-hold settling time permit the high sampling rates needed in applications such as radar and communications. Other specifications, such as the 1.4ps aperture jitter, 15mV pedestal offset, and -74dBc harmonic distortion are similarly supportive of A/D system performance goals. The CLC942 is fully compatible with demanding flash A/D input requirements as demonstrated by its ±2.2V output range and its ability to drive up to 90pF loads.

The CLC942 is constructed using thin film resistor/bipolar transistor technology as well as custom integrated circuits. The CLC942AI is specified over a temperature range of -25°C to +85°C, while the CLC942AM is specified over a range of -55°C to +125°C. Both devices are packaged in a 24-pin, 600 mil wide, ceramic DIP.

FEATURES (typical):
• 25ns hold-to-track acquisition time (0.01%)
• 5ns track-to-hold settling time
• 1.4ps aperture jitter
• 70MHz small-signal bandwidth
• 78dB feedthrough rejection
• ECL control signal

NOTES:
1. Parameters preceded by an * are the final electrical test parameters and are 100% tested. ABC units are tested at - 55°C, + 25°C, and + 125°C. AL units are tested only at + 25°C, although their performance is guaranteed at - 25°C and + 85°C as indicated above.
2. For optimum performance, differential voltage between the input and the output should not exceed 3V in HOLD mode.
3. Absolute Maximum Ratings are limiting values, to be applied individually, and beyond which the serviceability of the circuit may be impaired. Functional operation under any of these conditions is not necessarily implied. Exposure to absolute maximum ratings for extended periods may affect device reliability.
4. Junction-to-Case temperature rise is approximately 16°C; θ JA = 35°C/W.

Layout Considerations

For optimum performance from any precision, high-speed, track-and-hold, such as the CLC942, a high-quality printed circuit board layout is required. The main facet of the printed circuit board is a substantial ground plane around and under the CLC942. The ground plane will serve two main purposes, that of partially shielding the CLC942 from other system signals, as well as providing both power supply and signal return paths.

The input and output signals of the CLC942 should be controlled impedance transmission line such as stripline or micro-stripline for optimum performance (including the use of surface-mount termination components). In any case, as much attention must be paid to the ground return path as to the signal path itself. In general, a ground path at least 250 mils wide should provide an adequate ground return, but the stripline techniques are strongly recommended for high-frequency applications.

All supply lines to the CLC942 should be individually decoupled with 0.1μF capacitors. These decoupling capacitors should be located as close to the supply pins as possible. In addition, the decoupling capacitor lead lengths must also be kept to a minimum to avoid any effects from lead inductance. A better solution is the use of chip capacitors located right at the supply pins.

The use of sockets is not recommended with the CLC942, in that they tend to increase lead-to-lead capacitance as well as lead inductance, both degrading performance. If sockets must be used, low-profile Teflon types or individual “pin” sockets are preferred.

Track/Hold Switching Control

At the heart of the CLC942 is an active bipolar transistor bridge circuit. This bridge circuit allows the input signal to pass through to the HOLD capacitor during the signal acquisition mode, and isolates the HOLD capacitor during the HOLD mode. A differential driver circuit determines the state of the bridge circuit, either “open” or “closed.”

In normal mode, only the HOLD side of the bridge driver circuit is used. With the resistor diode network between pins 4 and 6 of the CLC942 bias as in figure 1, the HOLD input (pin 5) responds to standard 10K and 10K high ECL signals. At room temperature, 100K ECL logic family devices may also work with the CLC942, but their use is not guaranteed nor recommended.

By re-biasing the resistor/diode network between pins 4 and 6, the CLC942 will respond to standard TTL level logic families (Figure 2). The resistors tied to pin 6 and +5.0V, effectively raises the internal threshold level to +1.4V for use with TTL compatible devices. The three series diodes on pin 5 provide over-voltage protection for the inputs of the bridge driver circuit. For optimum dynamic performance from the CLC942, use of the more modern TTL families is recommended, such as the “AS” or “F” series.

The resistor/diode referenced network can be further modified for operation with “ground” referenced ac signals. Figure 3 illustrates the required connections, which amount to connecting both pins 4 and 6 to ground. The CLC942 will then operate from a 10Vpp, HOLD input signal. With the 50Ω input termination resistor, the HOLD control signal can be either dc or ac coupled.
CLC942 Evaluation Board

An evaluation board (part number 730017) is available for the CLC942. The board is user-configurable for either TTL, ECL, or "ac-signal" control. Operational details are available below.

CLC942 Evaluation Board Schematic

DESCRIPTION:
The CLC922 is a 12-bit analog-to-digital converter subsystem, including 12-bit quantizer, internal track-and-hold, reference circuitry and error correction circuits. The CLC922 has been specifically designed to operate from dual supplies, +5V and -5.2V. Constructed using advanced thin-film technology, the CLC922 is built in a fully certified MIL-STD-1772 facility.

The CLC922 incorporates a complete two-pass subranging architecture, constructed from several high-speed building blocks. A broadband (70MHz) input amplifier buffers input signals and provides an accurate drive signal to the on-board track-and-hold. Laser trimmed gain and offset circuits assure accurate matching unit to unit, while also offering broad flexibility in both gain and offset adjustment. Gain adjustment range is ±10%, with the 2Vpp input range adjustable over a +1V to -2V range. The latched outputs of the CLC922 mean that only a convert clock, analog input and power supplies are required for operation; internal logic generates all required timing signals.

Comprehensive dynamic testing on every part ensures that system performance goals will be met. The spurious-free-signal-range of 73.5dB@404kHz and 66.6dB@4.99MHz give an effective dynamic range of 12.0 bits and 10.8 bits respectively. This, coupled with an SNR specification of 66.6dB@4.99MHz, means that the CLC922 is ideally suited for use in areas like radar, instrumentation, and medical signal processing.

The CLC922BI is specified over a temperature range of -25°C to +85°C, while the CLC922B8C is specified over a range of -55°C to +125°C. Both devices are packaged in 40-pin, 1.1 inch wide, ceramic DIP's (note: leads are side brazed for easy access and inspection).

All versions of the CLC922 are manufactured in Comlinear's MIL-STD-1772 certified factory in Fort Collins, Colorado, U.S.A.

FEATURES (typical):
- 66.6dB spurious free signal range; fIn = 5MHz
- no missing codes guaranteed
- 0.35LSB differential linearity
- small package (2.28in²)
- low power dissipation 4W

Analog-to-Digital converters are specified in many ways. As a component achieves higher performance, its specifications and their definitions can become more critical. Fortunately, the vast number of converter applications can generally be placed into one of two classes. These are processed data and non-processed data applications. The distinction seems quite simple but the split implies a completely different approach in specifying A/D converters for a given application.

The processed data area includes the frequency domain applications which employ Fourier processing (FFT). Also in this category are the highly averaged applications, usually concerned with low noise. In each case, the converter’s data is averaged or convolved mathematically. This processing reduces the apparent noise level in the output data. For FFTs, the noise is simply spread over a large number of frequency bins. For simple averaging approaches, the gaussian distribution of noise is greatly reduced, appearing to increase the converter’s resolution. Processed applications include radar, network and spectrum analyzers, communications receivers, etc.

The non-processed applications tend to take the converter’s data in its original form with very little processing. This means that the noise reduction benefits of the processed applications are not seen. The non-processed area is composed primarily of time domain applications like imaging, DSO’s, ultrasound, etc.

The processed vs. non-processed issue has several implications in terms of converter specifications. For the non-processed (time domain) systems the dominant converter specifications deal with noise (SNR) and converter accuracy (DNL). The converter’s quantization noise and input stage noise dominate converter accuracy. The harmonic distortion (primarily INL) of the converter is generally of little interest given that most time domain applications present data for visual analysis and tend to focus on "local" accuracy rather than over the full input range. "Local" accuracy is best described through the standard noise measurements, such as SNR and DNL.

In the frequency domain application areas, the noise of the converter is processed to the point where, for almost all systems, it is no longer of issue. This is manifested as a reduction in the apparent noise floor. The actual RMS noise is not reduced, but is spread over more and more frequency bins as processing levels are increased. Unfortunately, the harmonic distortion performance of the converter is not affected by increased processing. This makes the harmonic performance, or more specifically the spurious performance, the dominant error source for frequency domain applications. SFDR becomes the dominant specification for determining converter performance in the frequency domain.

Signal-to-Noise Ratio (SNR) is the ratio of the power contained in the fundamental signal compared to the power contained in the entire noise floor. That is to say all individual noise components are added together to arrive at an integrated noise power. For SNR, harmonic power is excluded from the noise measurement. SNR is particularly important in time domain applications like digital image processing and infrared imaging, where conversion accuracy can be heavily degraded by integrated noise.

Signal-to-Noise-and-Distortion (SINAD) is the ratio of the fundamental signal power to the power at all other frequencies. This includes all noise as well as all harmonics. SINAD is a worst case specification for A/D converters, combining variables from both frequency and time domains. The value of SINAD in high-performance converter applications is not clear since it does not accurately predict the best converter for a given application. Because applications tend to fall into time domain/non-processed or frequency domain/processed applications, those specifications more directly related to the application should be the primary focus in selecting the converter.

Total Harmonic Distortion (THD) is the combined power of a specified number of harmonics, compared to the power of the fundamental signal. Harmonics are located at predictable frequencies, spaced at integer multiples of the fundamental signal. For example, a 1MHz fundamental would generate harmonics at 2MHz, 3MHz, 4MHz, ... and so on. In practice, only the first five harmonics contribute significantly to THD, although more may be included in the measurement. THD does not tend to apply well in frequency domain applications which are by their nature very SFDR oriented. In time domain applications, THD is indicative of full-scale input range distortion, however the high-performance time domain applications are generally most interested in local distortion performance. Local distortion and accuracy is dominated by DNL. The use of THD for applications requiring local performance is not likely to yield accurate or repeatable results in selecting the correct converter.

Spurious-Free-Signal-Range (SFSR) is the “clean” dynamic range of the converter, free from harmonic and spurious signals. SFSR is ratio of the power of the fundamental compared to the power of the next largest component in the frequency spectrum. The SFSR specification is especially important to frequency domain applications which perform Fourier transforms to analyze the converter’s output data. Processed applications like radar and network analyzers are typical areas where SFSR offers a direct prediction of converter’s performance at both the system and component levels. SFSR is the single best specification for selecting a converter to be used in a frequency domain application.

In-Band Harmonics (IBH) is the ratio of the power of the fundamental compared to the power of the single largest harmonic. This specification is very similar to SFDR, but since it only considers a fairly limited number of harmonics, it is potentially an incomplete gauge of converter performance. SFDR is more stringent and should be used whenever possible in lieu of IBH.
Typical Performance Characteristics (10MSPS unless specified)

CLC922 Operation
The CLC922 is a complete 12-bit 10MSPS A/D converter system. It includes input buffering, an internal track and hold amplifier, and references needed in a high-accuracy A/D system. The user need only apply power, ground, an input signal, and a convert signal to obtain 12-bit data every 100ns. Below is a block diagram of the converter:

CLC922 Block Diagram

The CLC922 uses the subranging A/D architecture, providing both high speed and high accuracy. This is the architecture of choice for A/D converters requiring high-speed and high resolution.

A conversion is initiated on the rising edge of the CONVERT signal, causing the internal T/H amplifier to switch from TRACK mode to HOLD mode. The internal two-pass quantizer will then convert the on-board track-and-hold signal into its digital equivalent. Approximately 25ns after the rising edge of CONVERT, new data will be latched into the output buffers. Since the CLC922 is a "pipelined" design, this data will be from the conversion two cycles before. Data from the present conversion will appear two cycles later (see timing diagram). The CLC922 incorporates several useful features including tri-statable outputs, offset adjust, gain adjust, and output data formatting. These features are detailed in the subsequent text.

T/H Output, V_ref, and Test Points (D.N.C.)
Several internal nodes are brought out of the package. Most of these are test points and should not be connected. Doing so may severely degrade performance or cause internal damage. The exceptions to this are the T/H output and the A/D reference voltage output, both of which are available to the user. Obviously, these nodes are critical to A/D performance and must be used with care — this is particularly true of the inverted T/H output (0V to -2.0V), which should normally be left unconnected.

The use of the -2.000V reference voltage output, on the other hand, is strongly encouraged. The reference output is a highly-stable voltage source, which can drive as little as 1kΩ at full accuracy. (Note: V_ref voltage output has been designed for tracking stability. Some variation in the precise output level is possible with various gain adjustment settings.)

Input Range and Offset Adjustment
The input range of the CLC922 is laser trimmed to 2V pp centered around ground (± 1V). Additional flexibility has been built into the CLC922 by allowing negative unipolar operation (negative unipolar . . . -2V to 0V). The input offset is determined by the voltage at pin 36.

<table>
<thead>
<tr>
<th>offset adjust voltage (pin 36)</th>
<th>analog input range</th>
</tr>
</thead>
<tbody>
<tr>
<td>GND</td>
<td>-1V to +1V</td>
</tr>
<tr>
<td>-2V</td>
<td>-2V to GND</td>
</tr>
</tbody>
</table>

The 2V pp input range of the CLC922 may be placed anywhere within the 1V to -2V window.

The offset adjustment pin should be driven from a voltage source that both exhibits a low impedance and is free of excessive noise. A voltage divider between power supplies fails both of these requirements. An elegant approach for this design is to use the CLC922's built-in 2V reference (pin 35). It may be connected directly to the offset adjust pin for a -2V to GND range or it may be used as shown below. The circuit below generates +2V by inverting the -2V reference voltage output. This +2V output may be used directly to provide an input signal range of GND to +2V. The +2V may also be used in conjunction with the -2V output and a potentiometer to provide maximum flexibility in setting the input range and adjusting the offset (as it is below). The unity-gain buffering op amp is needed to drive the adjustment pin with a low impedance.

Adjusting the Full-Scale Range
The 2V full-scale analog input range may be adjusted by up to ± 10%. As with the offset adjust pin, the gain adjust pin has a ±2V input range. A voltage of -2V compresses the full scale range by 10%. In other words, with -2V applied to the gain adjust pin, the full scale range is 1.8V. (This effectively increases the gain of the converter by 10%).
Conversely, applying +2V to the gain adjust pin expands the full scale range to 2.2V. (This effectively decreases the gain of the converter by 10%.) In each case, the expansion or compression is symmetric about “0” – both FS and –FS change. In practice, this means the gain adjustments should be made before the offset is adjusted.

<table>
<thead>
<tr>
<th>gain adjust voltage (pin 33)</th>
<th>analog input range</th>
</tr>
</thead>
<tbody>
<tr>
<td>GND</td>
<td>2V_{pp}</td>
</tr>
<tr>
<td>−2V</td>
<td>1.8V_{pp}</td>
</tr>
<tr>
<td>+2V</td>
<td>2.2V_{pp}</td>
</tr>
</tbody>
</table>

The circuit considerations which apply to the offset adjust pin also apply to the gain adjust pin (i.e., low source impedance and low noise); the offset adjust circuit may also be used for gain adjustments as indicated on the schematic. If flexibility is desired for both offset and gain adjust, an additional 10kΩ potentiometer and unity gain buffering op amp may be added.

**Auto-Calibration**

Many systems benefit from the ability to dynamically adjust offset and/or the gain. This is easily accomplished by incorporating a D/A converter into the adjustment circuit above. The computer system drives the D/A and thereby adjusts the voltage applied to the offset and/or the gain adjust pins. Gain adjustments should be made before any offset adjustments.

**Simple DAC’s provide Auto-cal Capability**

**Using a Balun for Impedance Control**

Harsh environments may have an excessive amount of noise on signal and ground lines. Much of this type of “common mode” noise can be eliminated from the analog signal path through the use of a balun. A balun is a 1:1 impedance matching transformer which forces equal currents in both the signal and ground paths, forming a common mode choke. The inputs of the balun may be driven from either an isolated signal and ground, or a differential driver; either is acceptable.

A balun is constructed from approximately ten turns of twisted wire (#26 or #28 AWG) wound around a powdered iron toroid. This 1:1 impedance matching circuit should also minimize ground-loop effects.

**Timing Considerations**

The CLC922 is designed to provide up to 10MSPS (10 million samples per second). This is equivalent to 100ns per conversion cycle. After the rising edge of the CONVERT signal (which initiates the actual conversion cycle), the on-board track-and-hold will move from TRACK mode to HOLD mode, followed by a two-step conversion process. Data is “pipelined” within the CLC922, meaning that data from a specific conversion will take two more conversion cycles to make its way to the CLC922 outputs (see timing diagram page 5).

The conversion cycle ends approximately 30ns after rising edge of CONVERT. The CONVERT pulse should remain HIGH during this 30ns interval to prevent the clock transition from corrupting the conversion cycle accuracy. On the other end of the CONVERT cycle (prior to the rising edge which initiates the next conversion cycle), the LOW period should also be at least 40ns long. The on-board track-and-hold will move from HOLD mode to TRACK mode soon after the falling edge of CONVERT. The CLC922 requires just less than 40ns of track time for rated performance, hence the 40ns CONVERT pulse width LOW requirement. Both t_{PHL} and t_{PLH} for CONVERT may be extended much longer in time, although no increase in conversion accuracy should be expected.
There is no lower bound for the CLC922 conversion rate. In other words "dc" clocks are acceptable, but the edge transition times should be less than 20ns for proper operation.

**Convert Clock Considerations**

The CLC922 requires a TTL level clock signal to control the conversion timing. On each rising edge of the CONVERT signal, the CLC922 will initiate a conversion sequence. The quality and purity of the clock signal has a major impact on the quality and accuracy of the conversion process. Essentially what the CLC922 requires is an extremely low jitter clock source, at least as good as the CLC922 aperture jitter specification at 4.5ps(rms). Excessive jitter will manifest itself as broad-band noise, severely degrading the converter's accuracy.

The low clock jitter requirements eliminate nearly all commercial pulse generators, and most signal sources, at least in terms of their direct output. A simple method of "squaring up" low-jitter clock signals, is to use a narrow-band pass filter to generate a pure sine wave at the conversion frequency. This signal is then "squared up" using a modified ECL-to-TTL translator. This technique should allow most low-jitter signal sources to be used without loss of conversion accuracy. A detailed circuit is illustrated below.

![SINE to TTL Conversion Circuit Diagram](image)

If the signal-to-noise ratio is below expectations and the input signal is not noisy, clock jitter should be investigated.

\[ SNR_{\text{MAX}} = 20 \log \left( \frac{1}{2\pi T_{\text{in}} \text{ Jitter}_{\text{RMS}}} \right) \]

where...

\[ \text{Jitter}_{\text{RMS}} = \sqrt{(\text{Clock Jitter}_{\text{RMS}})^2 + (\text{Analog Jitter}_{\text{RMS}})^2} \]

**Crystal Sources**

Standard crystal controlled TTL oscillators are a very cost-effective and a convenient source of high purity clock signals. The inherently low jitter present in such sources is ideal for ADC testing and evaluation. Additionally, crystal sources are an excellent source, once filtered, for use as an analog input signal, particularly in test and evaluation applications.

**Output Latching**

The CLC922 output data will, in most cases, be placed in a buffer memory prior to further processing. This may require higher digital drive capability than the CLC922 can provide. To overcome this, output latches should be placed just after the CLC922.

---

**Low Jitter Crystal Source with Bandpass Filtering**

The timing of these latches can play a major role in the conversion accuracy. Some of the issues involved here are minimizing digital feedthrough to the analog signal, digital corruption of the conversion process, digital corruption of the output data, and proper setup and hold time condition.

**Data Ready**

The most critical portion of the conversion cycle is the 30ns after the rising edge of CONVERT (the actual conversion period) and the 15ns window just before the rising edge of CONVERT (the final track-and-hold setting period just prior to the conversion). Any digital switching, latches or otherwise, may seriously undermine the CLC922 conversion accuracy. In other words ... the use of the CONVERT Clock (rising edge) as a DATA READY signal, may inject digital switching noise back onto the analog input signal.

Using the rising edge of CONVERT for a DATA READY signal means that no more than 10ns of hold time is available to external logic. On the other hand, assuming 10MSPS and a 50% duty cycle CONVERT clock, better than 40ns of setup time is available with 60ns hold time, provided the falling edge of CONVERT is used as a DATA READY.

The falling edge DATA READY will place latch and bus transitions after the internal conversion cycle, but also well before the critical final setting interval for the on-board track-and-hold. This technique is particularly effective when used with a 50% duty cycle CONVERT clock. Assuming the worst-case timing at 10MSPS operation, the falling edge of CONVERT used as a DATA READY will be approximately 20ns after the internal conversion is complete, and a full 20ns before the on-board track-and-hold enters track mode for the next cycle. This should allow switching transients to die down, even in a very noisy digital system, before the next analog digitization takes place.

---

**Recommended Latch/DATA READY Timing**

*Note that when the falling edge of convert is used to clock subsequent logic, that no digital transitions occur during the analog conversion period (shaded region ±30ns around the rising edge of convert)*
Output Coding
The CLC922 offers two output coding formats, Offset Binary and Two’s Complement. “Offset Binary” assumes a bipolar input range for convenience, but essentially it denotes all zeroes for the most negative input representation, and all ones for the most positive input representation. The Two’s Complement format also assumes a bipolar input, but inverts D1 (MSB) to provide the proper coding.

Both output formats function normally if offset input ranges are employed (i.e., unipolar or negative). The selection of output formats is made by choosing whether D1 (MSB) or D1 (MSB) is used as a data output.

Grounding
All of the CLC922 grounds are internally connected. Pins 1, 6, 21, and 40 are connected through the package itself; these are further connected to all other ground pins by way of the substrate and bond wires.

The CLC922 has been designed to incorporate a single ground plane for both digital and analog return currents. A “split” ground plane (one for digital components and another for analog components) is not recommended. Although a split ground approach is not recommended, certain types of systems preclude the use of a single ground plane. For these systems, the following chart matches signals and return currents so that the most appropriate grounding choices can be made.

NOTE: Pins 1, 6, 21, and 40 are connected through the package metalization itself.

Power Supplies and Decoupling
The CLC922 does not require separate analog and digital power supplies as is often recommended for high-performance data converters. The design is well-balanced internally and includes on-board decoupling capacitors. As with any high-performance circuit, supply variations can degrade performance. DC variation of supplies, within the rated ±5% range, should have only a minimal effect on performance. AC supply variation can be more troublesome. The CLC922 operates with a power supply rejection ratio (PSRR) of better than –50dB. Even so, adequate supply decoupling will help to ensure rated performance.

The recommended supply decoupling scheme is as follows:

Option #1: One 0.1μF ceramic capacitor at each supply pin, with a 5-10μF electrolytic or tantalum for each of the three main supply feeds (proximity not critical).

Option #2: One 0.1 to 0.033 chip capacitor at each supply pin, with a 5-10μF electrolytic or tantalum for each of the three main supply feeds (proximity not critical).

Please note that supply feeds, with excessive digital switching noise from other sources, may require additional filtering.

Layout Considerations
The CLC922 has been designed to be easily accommodated on a printed circuit board; for example, the inputs enter one side of the package and the outputs leave on the opposite side, with the analog and digital connections widely separated from one another. The PC board should exhibit similar layout guidelines. If the analog input signal has had to travel more than a few inches to reach the analog input pin (VIN), proper termination techniques should be followed to avoid reflections caused by improper impedance matching. Special care should also be exercised to place external output latches close to the CLC922 digital outputs.

Sockets are not recommended, in that they increase both lead inductance and inter-lead capacitance. If sockets must be used, Teflon or “pin” type sockets should minimize this effect. Additionally, the “Recommended Power Supply Decoupling Scheme” illustrates an effective bypass arrangement. Chip capacitors are preferred and should be located as close as practical to the individual supply pins.

CLC922 Evaluation Board Support
An evaluation board (Comlinear part number 730015) is available for the CLC922 at minimal cost. It is designed to provide a simple platform for evaluating the CLC922.

Applications Assistance
Comlinear maintains a staff of R&D-level applications engineers, who are available for design and applications assistance at (303) 226-0500.

DESCRIPTION
The CLC925 is a 12-bit analog-to-digital converter subsystem, including 12-bit quantizer, internal track-and-hold, reference circuitry and error correction circuits. The CLC925 is constructed using advanced thin-film technology, and is built in a fully certified MIL-STD-1772 facility.

The CLC925 incorporates a complete two-pass subranging architecture, constructed from several high-speed building blocks. A broadband (70MHz) input amplifier buffers input signals and provides an accurate drive signal to the on-board track-and-hold. Laser trimmed gain and offset circuits assure accurate matching unit to unit, while also offering broad flexibility in both gain and offset adjustment. Gain adjustment range is ±10%, with the 2V<sub>pp</sub> input range adjustable over a ±2V range. The latched outputs of the CLC925 mean that only a convert clock, analog input and power supplies are required for operation; internal logic generates all required timing signals.

Comprehensive dynamic testing on every part ensures that system performance goals will be met. The spurious-free-signal range of 74.2dB@404kHz and 66.8dB@4.99MHz give an effective dynamic range of 12.0 bits and 10.8 bits respectively. This, coupled with an SNR specification of 66.6dB@4.99MHz, means that the CLC925 is ideally suited for use in areas like radar, instrumentation, and medical signal processing.

The CLC925BI is specified over a temperature range of -25°C to +85°C, while the CLC925B8C is specified over a range of -55°C to +125°C. Both devices are packaged in 40-pin, 1.1 inch wide, ceramic DIP's (note: leads are side brazed for easy access and inspection).

### FEATURES (typical):
- 66.8dB spurious free signal range; f<sub>IN</sub>=5MHz
- no missing codes guaranteed
- 0.35LSB differential linearity
- small package (2.28in<sup>2</sup>)
- low power dissipation 4.2W

  - 40kHz; FS: 59 61 61 db (SND1)
  - 4.996MHz; FS: 59 61 61 db (SND2)
- **signal-to-noise and distortion (SFSR)**
  - 40kHz; FS: 74.2 60.5 64 64 dB (SFSR1)
  - 4.996MHz; FS: 66.8 59 61.5 60 dB (SFSR2)
- **effective bits** (based on SFSR)
  - 40kHz; FS: 12.0 9.75 10.33 10.33 bits (SFEB1)
  - 4.996MHz; FS: 10.8 9.50 9.92 9.67 bits (SFEB2)
- **effective bits** (based on SINAD)
  - 40kHz; FS: 10.50 9.50 9.84 9.84 bits (EB1)
  - 4.996MHz; FS: 10.00 9.17 9.50 9.09 bits (EB2)

#### DC ACCURACY and PERFORMANCE

- **differential non-linearity** dc; FS
  - 0.35 1.0 LSB (DNL)
- **integral non-linearity** dc; FS
  - 1.2 4.0 LSB (INL)
- **missing codes**
  - 0 codes (MC)
- **bipolar offset error**
  - 3.4 mV (VIO)
  - temperature coefficient
  - 0.035 °C (DVIO)
- **bipolar gain error**
  - 0.3 %FS (GE)
  - temperature coefficient
  - 0.035 %FS/°C (DGE)
- **reference voltage output**
  - -2.000 V (VREF)

#### ANALOG INPUT PERFORMANCE

- **analog input bias current**
  - 10 45 25 35 μA (IBN)
- **temperature coefficient**
  - 100 250 nA/°C (DIBN)
- **analog input resistance**
  - 80 > 25 kΩ (RIN)
- **analog input capacitance**
  - 3.5 5.5 5.5 pF (CIN)

#### POWER REQUIREMENTS

- **supply current** (+ \( V_{cc} = +5.0V \)) 10MSPS; no load
  - 318 410 385 360 mA (ICC)
- **supply current** (- \( V_{ee} = -5.2V \)) 10MSPS; no load
  - 454 700 630 550 mA (IEE)
- **nominal power dissipation** 10MSPS; no load
  - 4.2 W (PD)

**Notes:**

1. Parameters preceded by an * are the final electrical test parameters and are 100% tested. B8C units are tested at -55°C, +25°C, and +125°C. Parameters preceded by a + are 100% tested on B8C units only. BI units are tested only at +25°C although their performance is guaranteed at -25°C and +85°C as indicated above.

2. Absolute maximum ratings are limiting values, to be applied individually, and beyond which the serviceability of the circuit may be impaired. Functional operability under any of these conditions is not necessarily implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.

3. Operation down to 11V is possible with negligible degradation in performance.

4. Junction temperature rise above case = 16°C; \( T_{ja} = 16°C/W \); \( T_{ja} = 7°C/W \) @ 500LFPM. (Use of a SIL-PAD* #550007, from Berquist (800-347-4572), can lower case-to-ambient rise: \( T_{ja} = 12°C/W \) @ still air ~ 12in² ground plane; \( T_{ja} = 3.4°C/W \) @ 100LFPM ~ 12in² ground plane.)

10 - 17
Analog-to-Digital converters are specified in many ways. As a component achieves higher performance, its specifications and their definitions can become more critical. Fortunately, the vast number of converter applications can generally be placed into one of two classes. These are processed data and non-processed data applications. The distinction seems quite simple but the split implies a completely different approach in specifying A/D converters for a given application.

The processed data area includes the frequency domain applications which employ Fourier processing (FFT). Also in this category are the highly averaged applications, usually concerned with low noise. In each case, the converter's data is averaged or convolved mathematically. This processing reduces the apparent noise level in the output data. For FFTs, the noise is simply spread over a large number of frequency bins. For simple averaging approaches, the gaussian distribution of noise is greatly reduced, appearing to increase the converter's resolution. Processed applications include radar, network and spectrum analyzers, communications receivers, etc.

The non-processed applications tend to take the converter's data in its original form with very little processing. This means that the noise reduction benefits of the processed applications are not seen. The non-processed area is composed primarily of time domain applications like imaging, DSO's, ultrasound, etc.

The processed vs. non-processed issue has several implications in terms of converter specifications. For the non-processed (time domain) systems the dominant converter specifications deal with noise (SNR) and converter accuracy (DNL). The converter's quantization noise and input stage noise dominate converter accuracy. The harmonic distortion (primarily INL) of the converter is generally of little interest given that most time domain applications present data for visual analysis and tend to focus on "local" accuracy rather than over the full input range. "Local" accuracy is best described through the standard noise measurements, such as SNR and DNL.

In the frequency domain application areas, the noise of the converter is processed to the point where, for almost all systems, it is no longer of issue. This is manifested as a reduction in the apparent noise floor. The actual RMS noise is not reduced, but is spread over more and more frequency bins as processing levels are increased. Unfortunately, the harmonic distortion performance of the converter is not affected by increased processing. This makes the harmonic performance, or more specifically the spurious performance, the dominant error source for frequency domain applications. SFSR becomes the dominant specification for determining converter performance in the frequency domain.

Signal-to-Noise Ratio (SNR) is the ratio of the power contained in the fundamental signal compared to the power contained in the entire noise floor. That is to say all individual noise components are added together to arrive at an integrated noise power. For SNR, harmonic power is excluded from the noise measurement. SNR is particularly important in time domain applications like digital image processing and infrared imaging, where conversion accuracy can be heavily degraded by integrated noise.

Signal-to-Noise-and-Distortion (SINAD) is the ratio of the fundamental signal power to the power at all other frequencies. This includes all noise as well as all harmonics. SINAD is a worst case specification for A/D converters, combining variables from both frequency and time domains. The value of SINAD in high-performance converter applications is not clear since it does not accurately predict the best converter for a given application. Because applications tend to fall into time domain/non-processed or frequency domain/processed applications, those specifications more directly related to the application should be the primary focus in selecting the converter.

Total Harmonic Distortion (THD) is the combined power of a specified number of harmonics, compared to the power of the fundamental signal. Harmonics are located at predictable frequencies, spaced at integer multiples of the fundamental signal. For example, a 1MHz fundamental would generate harmonics at 2MHz, 3MHz, 4MHz, ... and so on. In practice, only the first five harmonics contribute significantly to THD, although more may be included in the measurement. THD does not tend to apply well in frequency domain applications which are by their nature very SFSR oriented. In time domain applications, THD is indicative of full-scale input range distortion, however the high-performance time domain applications are generally most interested in local distortion performance. Local distortion and accuracy is dominated by DNL. The use of THD for applications requiring local performance is not likely to yield accurate or repeatable results in selecting the correct converter.

Spurious-Free-Signal-Range (SFSR) is the "clean" dynamic range of the converter, free from harmonic and spurious signals. SFSR is ratio of the power of the fundamental compared to the power of the next largest component in the frequency spectrum. The SFSR specification is especially important to frequency domain applications which perform Fourier transforms to analyze the converter's output data. Processed applications like radar and network analyzers are typical areas where SFSR offers a direct prediction of converter's performance at both the system and component levels. SFSR is the single best specification for selecting a converter to be used in a frequency domain application.

In-Band Harmonics (IBH) is the ratio of the power of the fundamental compared to the power of the single largest harmonic. This specification is very similar to SFSR, but since it only considers a fairly limited number of harmonics, it is potentially an incomplete gauge of converter performance. SFSR is more stringent and should be used whenever possible in lieu of IBH.

### TTL-level Digital Inputs

**CONV**  
“Convert Command” begins a new conversion with a rising edge.

**ÖE**  
“Output Enable” is an active low input which causes the digital outputs to leave their high-impedance state.

### TTL-level Digital Outputs

**D1-D12**  
Digital data output. D1 is the MSB and D12 is the LSB.

**D1**  
Inverted version of the MSB, which is used for two's complement coding.

### Analog Input

**V<sub>in</sub>**  
Analog input with 2V<sub>pp</sub> input range which can be placed anywhere in a -2V to +2V range. See offset adjust pin.

**Gain Adjust**  
This input has a +2V to -2V input range and scales the 2V<sub>pp</sub> analog input range by +10% or -10% respectively. Gain adjustments should be made prior to offset adjustments, or an iterative technique will be required. If this feature is not used, this pin should be grounded.

**Offset Adjust**  
This pin has a ±2V input range and is used to translate the 2V<sub>pp</sub> analog input anywhere in the -2V to +2V range, as well as to provide a facility for adjusting the DC offset of the part. Offset adjust is slightly dependent on the gain adjustment setting; offset adjustments should be made after any gain adjustments have been completed. This pin should be grounded if it is not used.

### Miscellaneous

**V<sub>ref</sub>**  
V<sub>ref</sub> is a high stability -2.000V voltage reference, although its precise value varies with specific gain adjust settings (see text).

**D.N.C.**  
Do not connect!

**T/H output**  
This pin brings the internal T/H voltage out of the package through a 950Ω source impedance. The T/H output voltage is an inverted representation of the input signal, ranging from 0V to -2.0V. Normally this pin should be left unconnected.

### Power and Ground

+5V, +15V, -5.2V & GND
**CLC925 Operation**

The CLC925 is a complete 12-bit 10MSPS A/D converter system. It includes input buffering, an internal track and hold amplifier, and references needed in a high-accuracy A/D system. The user need only apply power, ground, an input signal, and a convert signal to obtain 12-bit data every 100ns. Below is a block diagram of the converter:

![CLC925 Block Diagram](image)

The CLC925 uses the subranging A/D architecture, providing both high speed and high accuracy. This is the architecture of choice for A/D converters requiring high-speed and high resolution.

A conversion is initiated on the rising edge of the CONVERT signal, causing the internal T/H amplifier to switch from TRACK mode to HOLD mode. The internal two-pass quantizer will then convert the on-board track-and-hold signal into its digital equivalent. Approximately 25ns after the rising edge of CONVERT, new data will be latched into the output buffers. Since the CLC925 is a "pipelined" design, this data will be from the conversion two cycles before. Data from the present conversion will appear two cycles later (see timing diagram). The CLC925 incorporates several useful features including tri-statable outputs, offset adjust, gain adjust, and output data formatting. These features are detailed in the subsequent text.

**T/H Output, V_{ref} and Test Points (D.N.C.)**

Several internal nodes are brought out of the package. Most of these are test points and should not be connected. Doing so may severely degrade performance or cause internal damage. The exceptions to this are the T/H output and the A/D reference voltage output, both of which are available to the user. Obviously, these nodes are critical to A/D performance and must be used with care – this is particularly true of the inverted T/H output (0V to -2.0V), which should normally be left unconnected.

The use of the -2.000V reference voltage output, on the other hand, is strongly encouraged. The reference output is a highly-stable voltage source, which can drive as little as 1kΩ at full accuracy. (Note: V_{REF} voltage output has been designed for tracking stability. Some variation in the precise output level is possible with various gain adjustment settings.)

**Input Range and Offset Adjustment**

The input range of the CLC925 is laser trimmed to 2V_{pp} centered around ground (±1V). Additional flexibility has been built into the CLC925 by allowing both positive and negative unipolar operation (positive unipolar . . . 0V to +2V; negative unipolar . . . -2V to 0V). The input offset is determined by the voltage at pin 36.

<table>
<thead>
<tr>
<th>offset adjust voltage (pin 36)</th>
<th>analog input range</th>
</tr>
</thead>
<tbody>
<tr>
<td>GND</td>
<td>-1V to +1V</td>
</tr>
<tr>
<td>-2V</td>
<td>-2V to GND</td>
</tr>
<tr>
<td>+2V</td>
<td>GND to +2V</td>
</tr>
</tbody>
</table>

The 2V_{pp} input range of the CLC925 may be placed anywhere within the ±2V window.

The offset adjustment pin should be driven from a voltage source that both exhibits a low impedance and is free of excessive noise. A voltage divider between power supplies fulfills both of these requirements. An elegant approach for this design is to use the CLC925’s built-in 2V reference (pin 35). It may be connected directly to the offset adjust pin for a -2V to GND range or it may be used as shown below. The circuit below generates +2V by inverting the -2V reference voltage output. This +2V output may be used directly to provide an input signal range of GND to +2V. The +2V may also be used in conjunction with the -2V output and a potentiometer to provide maximum flexibility in setting the input range and adjusting the offset (as it is below). The unity-gain buffering op amp is needed to drive the adjustment pin with a low impedance.

**Input Range and Offset Adjust op amps**

Adjusting the Full-Scale Range

The 2V full-scale analog input range may be adjusted by up to ±10%. As with the offset adjust pin, the gain adjust pin has a ±2V input range. A voltage of -2V compresses the full scale range by 10%. In other words, with -2V applied to the gain adjust pin, the full scale range is 1.8V. (This effectively increases the gain of the converter by 10%.)
Conversely, applying +2V to the gain adjust pin expands the full scale range to 2.2V. (This effectively decreases the gain of the converter by 10%.) In each case, the expansion or compression is symmetric about "0"...both FS and -FS change. In practice, this means the gain adjustments should be made before the offset is adjusted.

<table>
<thead>
<tr>
<th>gain adjust voltage (pin 33)</th>
<th>analog input range</th>
</tr>
</thead>
<tbody>
<tr>
<td>GND</td>
<td>2V_{pp}</td>
</tr>
<tr>
<td>-2V</td>
<td>1.8V_{pp}</td>
</tr>
<tr>
<td>+2V</td>
<td>2.2V_{pp}</td>
</tr>
</tbody>
</table>

The circuit considerations which apply to the offset adjust pin also apply to the gain adjust pin (i.e., low source impedance and low noise); the offset adjust circuit may also be used for gain adjustments as indicated on the schematic. If flexibility is desired for both offset and gain adjust, an additional 10kΩ potentiometer and unity gain buffering op amp may be added.

**Auto-Calibration**

Many systems benefit from the ability to dynamically adjust offset and/or the gain. This is easily accomplished by incorporating a D/A converter into the adjustment circuit above. The computer system drives the D/A and thereby adjusts the voltage applied to the offset and/or the gain adjust pins. Gain adjustments should be made before any offset adjustments.

**Simple DAC's provide Auto-cal Capability**

**Using a Balun for Impedance Control**

Harsh environments may have an excessive amount of noise on signal and ground lines. Much of this type of "common mode" noise can be eliminated from the analog signal path through the use of a balun. A balun is a 1:1 impedance matching transformer which forces equal currents in both the signal and ground paths, forming a common mode choke. The inputs of the balun may be driven from either an isolated signal and ground, or a differential driver; either is acceptable.

A balun is constructed from approximately ten turns of twisted wire (#26 or #28 AWG) wound around a powdered iron toroid. This 1:1 impedance matching circuit should also minimize ground-loop effects.

The conversion cycle ends approximately 30ns after rising edge of CONVERT. The CONVERT pulse should remain HIGH during this 30ns interval to prevent the clock transition from corrupting the conversion cycle accuracy. On the other end of the CONVERT cycle (prior to the rising edge which initiates the next conversion cycle), the LOW period should also be at least 40ns long. The on-board track-and-hold will move from HOLD mode to TRACK mode soon after the falling edge of CONVERT. The CLC925 requires just less than 30ns of track time for rated performance, hence the 30ns CONVERT pulse width LOW requirement. Both t_{PWH} and t_{PWL} for CONVERT may be extended much longer in time, although no increase in conversion accuracy should be expected.
There is no lower bound for the CLC925 conversion rate. In other words "dc" clocks are acceptable, but the edge transition times should be less than 20ns for proper operation.

**Convert Clock Considerations**

The CLC925 requires a TTL level clock signal to control the conversion timing. On each rising edge of the CONVERT signal, the CLC925 will initiate a conversion sequence. The quality and purity of the clock signal has a major impact on the quality and accuracy of the conversion process. Essentially what the CLC925 requires is an extremely low jitter clock source, at least as good as the CLC925 aperture jitter specification at 4.5ps(rms). Excessive jitter will manifest itself as broad-band noise, severely degrading the converter’s accuracy.

The low clock jitter requirements eliminate nearly all commercial pulse generators, and most signal sources, at least in terms of their direct output. A simple method of “squaring up” low-jitter clock signals, is to use a narrow-band pass filter to generate a pure sine wave at the conversion frequency. This signal is then “squared up” using a modified ECL-to-TTL translator. This technique should allow most low-jitter signal sources to be used without loss of conversion accuracy. A detailed circuit is illustrated below.

**SINE to TTL Conversion Circuit**

If the signal-to-noise ratio is below expectations and the input signal is not noisy, clock jitter should be investigated.

\[
\text{SNR}_{\text{MAX}} = 20 \log \left( \frac{1}{2\pi f_{\text{in}} \text{Jitter}_{\text{RMS}}} \right)
\]

where...

\[
\text{Jitter}_{\text{RMS}} = \sqrt{\text{Clock Jitter}_{\text{RMS}}}^2 + \text{Analog Jitter}_{\text{RMS}}^2
\]

**Crystal Sources**

Standard crystal controlled TTL oscillators are a very cost-effective and a convenient source of high purity clock signals. The inherently low jitter present in such sources is ideal for ADC testing and evaluation. Additionally, crystal sources are an excellent source, once filtered, for use as an analog input signal, particularly in test and evaluation applications.

**Output Latching**

The CLC925 output data will, in most cases, be placed in a buffer memory prior to further processing. This may require higher digital drive capability than the CLC925 can provide. To overcome this, output latches should be placed just after the CLC925.

---

**Low Jitter Crystal Source with Bandpass Filtering**

The timing of these latches can play a major role in the conversion accuracy. Some of the issues involved here are minimizing digital feedthrough to the analog signal, digital corruption of the conversion process, digital corruption of the output data, and proper setup and hold time condition.

**Data Ready**

The most critical portion of the conversion cycle is the 30ns after the rising edge of CONVERT (the actual conversion period) and the 15ns window just before the rising edge of CONVERT (the final track-and-hold setting period just prior to the conversion). Any digital switching, latches or otherwise, may seriously undermine the CLC925 conversion accuracy. In other words... the use of the CONVERT Clock (rising edge) as a DATA READY signal, may inject digital switching noise back onto the analog input signal.

Using the rising edge of CONVERT for a DATA READY signal means that no more than 10ns of hold time is available to external logic. On the other hand, assuming 10MSPS and a 50% duty cycle CONVERT clock, better than 40ns of setup time is available with 60ns hold time, provided the falling edge of CONVERT is used as a DATA READY.

The falling edge DATA READY will place latch and bus transitions after the internal conversion cycle, but also well before the critical final setting interval for the on-board track-and-hold. This technique is particularly effective when used with a 50% duty cycle CONVERT clock. Assuming the worst-case timing at 10MSPS operation, the falling edge of CONVERT used as a DATA READY will be approximately 20ns after the internal conversion is complete, and a full 20ns before the on-board track-and-hold enters track mode for the next cycle. This should allow switching transients to die down, even in a very noisy digital system, before the next analog digitization takes place.

**Recommended Latch/DATA READY Timing**

*Note that when the falling edge of convert is used to clock subsequent logic, that no digital transitions occur during the analog conversion period (shaded region ±30ns around the rising edge of convert)
Output Coding

The CLC925 offers two output coding formats, Offset Binary and Two's Complement. "Offset Binary" assumes a bipolar input range for convenience, but essentially it denotes all zeroes for the most negative input representation, and all ones for the most positive input representation. The Two's Complement format also assumes a bipolar input, but inverts D1(MSB) to provide the proper coding.

Both output formats function normally if offset input ranges are employed (i.e., unipolar, positive, or negative). The selection of output formats is made by choosing whether D1(MSB) or D1(1SB) is used as a data output.

NOTE: Pins 1, 6, 21, and 40 are connected through the package metalization itself.

Grounding

All of the CLC925 grounds are internally connected. Pins 1, 6, 21, and 40 are connected through the package itself; these are further connected to all other ground pins by way of the substrate and bond wires.

The CLC925 has been designed to incorporate a single ground plane for both digital and analog return currents. A "split" ground plane (one for digital components and another for analog components) is not recommended. Although a split ground approach is not recommended, certain types of systems preclude the use of a single ground plane. For analog components, a split ground approach is recommended.

Power Supplies and Decoupling

The CLC925 does not require separate analog and digital power supplies as is often recommended for high-performance data converters. The design is well-balanced internally and includes on-board decoupling capacitors. As with any high-performance circuit, supply variations can degrade performance. DC variation of supplies, within the rated ±5% range, should have only a minimal effect on performance. AC supply variation can be more troublesome. The CLC925 operates with a power supply rejection ratio (PSRR) of better than -50dB. Even so, adequate supply decoupling will help to ensure rated performance.

The recommended supply decoupling scheme is as follows:

Option #1: One 0.1μF ceramic capacitor at each supply pin, with a 5-10μF electrolytic or tantalum for each of the three main supply feeds (proximity not critical).

Option #2: One 0.1 to 0.033 chip capacitor at each supply pin, with a 5-10μF electrolytic or tantalum for each of the three main supply feeds (proximity not critical).

Please note that supply feeds, with excessive digital switching noise from other sources, may require additional filtering.

Layout Considerations

The CLC925 has been designed to be easily accommodated on a printed circuit board; for example, the inputs enter one side of the package and the outputs leave on the opposite side, with the analog and digital connections widely separated from one another. The PCB board should exhibit similar layout guidelines. If the analog input signal has had to travel more than a few inches to reach the analog input pin (V_{IN}), proper termination techniques should be followed to avoid reflections caused by improper impedance matching. Special care should also be exercised to place external output latches close to the CLC925 digital outputs.

Sockets are not recommended, in that they increase both lead inductance and inter-lead capacitance. If sockets must be used, Teflon or "pin" type sockets should minimize this effect. Additionally, the "Recommended Power Supply Decoupling Scheme" illustrates an effective bypass arrangement. Chip capacitors are preferred and should be located as close as practical to the individual supply pins.

CLC925 Evaluation Board Support

An evaluation board (Comlinear part number 730015) is available for the CLC925 at minimal cost. It is designed to provide a simple platform for evaluating the CLC925.

Applications Assistance

Comlinear maintains a staff of R&D-level applications engineers, who are available for design and applications assistance at (303) 226-0500.
Complete System Architecture with Offset and Gain Adjustment

APPLICATIONS:
• radar processing
• infrared processing/electronic imaging
• instrumentation
• medical imaging
• transient-signal recorders

DESCRIPTION:

The CLC935 is a 12-bit analog-to-digital converter hybrid, including voltage references, track-and-hold, and 12-bit quantizer with ECL compatible outputs. The CLC935 has been especially optimized for a Spurious-Free-Signal-Range of better than 70dB. The CLC935 is constructed using advanced thin-film hybrid technology in a fully certified MIL-STD-1772 facility.

Comprehensive dynamic testing on every part ensures that system performance goals will be met, including spurious-free-signal-range (SFSR) of 77dB from 408kHz to 7.22MHz. This, coupled with an SNR specification of 66.5dB@7.22MHz, means that the CLC935 is ideally suited for use in areas such as radar and instrumentation signal processing.

The CLC935 incorporates a complete two-pass subranging architecture, constructed from several high-speed building blocks. A broadband (135MHz) input amplifier buffers input signals and provides an accurate drive signal to the on-board track-and-hold. Laser trimmed gain and offset circuits assure accurate matching unit to unit. The latched outputs of the CLC935 mean that only a convert clock, analog input, and power supplies are required for operation; internal logic generates all required timing signals.

The CLC935AC is specified over a temperature range of 0°C to +70°C, while the CLC935A8C is specified over a range of -55°C to +125°C. Both devices are packaged in 40-pin, 1.1in wide, ceramic DIPs (note: leads are side brazed for easy access and inspection). Contact factory for availability of "gull-wing" surface-mount versions.

Features (typical):
• 77dB spurious free signal range; f_{\text{IN}} = 7.22MHz
• no missing codes guaranteed
• 0.7LSB differential linearity
• small package (2.28in²)

Ordering Information

CLC935AC 0°C to +70°C industrial version
CLC935A8C -55°C to +125°C MIL-STD-883, class B
DESC SMD 5960-92039

Both versions of the CLC935 are manufactured in Comlinear's MIL-STD-1772 certified facility in Fort Collins, Colorado, U.S.A.

Note 1: Parameters preceded by an * are 100% tested. AC units are tested at 25°C and guaranteed at 0°C and 70°C.

Note 2: Absolute maximum ratings are limiting values, to be applied individually, and beyond which the serviceability of the circuit may be impaired. Functional operability under any of these conditions is not necessarily implied. Exposure to maximum ratings for extended periods may affect device reliability.

Note 3: Junction temperature rise above case ~16°C; $t_{\text{ja}}=16^\circ\text{C/W}; t_{\text{ja}}=7^\circ\text{C/W}@500\text{LFPM}$. Use of a SIL-PAD# #550007, from Berquist (1-800-347-4572), can lower case-to-ambient rise; $t_{\text{ja}}=12^\circ\text{C/W}@\text{still air}, 12\text{in'}\text{ ground-plane}; t_{\text{ja}}=3.4^\circ\text{C/W}@100\text{LFPM}, 12\text{in'}\text{ ground-plane}.

Note 4: Planned product improvements are expected to lower -5.2V supply current, as well as nominal power dissipation.

Note: dV = fDV + Data Bit Skew
Analog-to-Digital converters are specified in many ways. As a component achieves higher performance, its specifications and their definitions can become more critical. Fortunately, the vast number of converter applications can generally be placed into one of two classes. These are processed data and non-processed data applications. The distinction seems quite simple but the split implies a completely different approach in specifying A/D converters for a given application.

The processed data area includes the frequency domain applications which employ Fourier processing (FFT). Also in this category are the highly averaged applications, usually concerned with low noise. In each case, the converter’s data is averaged or convolved mathematically. This processing reduces the apparent noise level in the output data. For FFTs, the noise is simply spread over a large number of frequency bins. For simple averaging approaches, the gaussian distribution of noise is greatly reduced, appearing to increase the converter’s resolution. Processed applications include radar, network and spectrum analyzers, communications receivers, etc.

The non-processed applications tend to take the converter’s data in its original form with very little processing. This means that the noise reduction benefits of the processed applications are not seen. The non-processed area is composed primarily of time domain applications like imaging, DSO’s, ultrasound, etc.

The processed vs. non-processed issue has several implications in terms of converter specifications. For the non-processed (time domain) systems the dominant converter specifications deal with noise (SNR) and converter accuracy (DNL). The converter’s quantization noise and input stage noise dominate converter accuracy. The harmonic distortion (primarily INL) of the converter is generally of little interest given that most time domain applications present data for visual analysis and tend to focus on “local” accuracy rather than over the full input range. “Local” accuracy is best described through the standard noise measurements, such as SNR and DNL.

In the frequency domain application areas, the noise of the converter is processed to the point where, for almost all systems, it is no longer of issue. This is manifested as a reduction in the apparent noise floor. The actual RMS noise is not reduced, but is spread over more and more frequency bins as processing levels are increased. Unfortunately, the harmonic distortion performance of the converter is not affected by increased processing. This makes the harmonic performance, or more specifically the spurious performance, the dominant error source for frequency domain applications. SFSR becomes the dominant specification for determining converter performance in the frequency domain.

Signal-to-Noise Ratio (SNR) is the ratio of the power contained in the fundamental signal compared to the power contained in the entire noise floor. That is to say all individual noise components are added together to arrive at an integrated noise power. For SNR, harmonic power is excluded from the noise measurement. SNR is particularly important in time domain applications like digital image processing and infrared imaging, where conversion accuracy can be heavily degraded by integrated noise.

Signal-to-Noise-and-Distortion (SINAD) is the ratio of the fundamental signal power to the power at all frequencies. This includes all noise as well as all harmonics. SINAD is a worst case specification for A/D converters, combining variables from both frequency and time domains. The value of SINAD in high-performance converter applications is not clear since it does not accurately predict the best converter for a given application. Because applications tend to fall into time domain/non-processed or frequency domain/processed applications, those specifications more directly related to the application should be the primary focus in selecting the converter.

Total Harmonic Distortion (THD) is the combined power of a specified number of harmonics, compared to the power of the fundamental signal. Harmonics are located at predictable frequencies, spaced at integer multiples of the fundamental signal. For example, a 1MHz fundamental would generate harmonics at 2MHz, 3MHz, 4MHz, ... and so on. In practice, only the first five harmonics contribute significantly to THD, although more may be included in the measurement. THD does not tend to apply well in frequency domain applications which are by their nature very SFSR oriented. In time domain applications, THD is indicative of full-scale input range distortion, however the high-performance time domain applications are generally most interested in local distortion performance. Local distortion and accuracy is dominated by DNL. The use of THD for applications requiring local performance is not likely to yield accurate or repeatable results in selecting the correct converter.

Spurious-Free-Signal-Range (SFSR) is the “clean” dynamic range of the converter, free from harmonic and spurious signals. SFSR is ratio of the power of the fundamental compared to the power of the next largest component in the frequency spectrum. The SFSR specification is especially important to frequency domain applications which perform Fourier transforms to analyze the converter’s output data. Processed applications like radar and network analyzers are typical areas where SFSR offers a direct prediction of converter’s performance at both the system and component levels. SFSR is the single best specification for selecting a converter to be used in a frequency domain application.

In-Band Harmonics (IBH) is the ratio of the power of the fundamental compared to the power of the single largest harmonic. This specification is very similar to SFSR, but since it only considers a fairly limited number of harmonics, it is potentially an incomplete gauge of converter performance. SFSR is more stringent and should be used whenever possible in lieu of IBH.

![Typical Frequency Spectrum and its Components](image-url)
Some of the performance plots that follow require more explanation than is feasible in the caption. This section goes into more detail as to how these plots were generated, and how they might be interpreted. Additional information can be found in the application note AD-01. Designing with High-Performance A/D converters

**Spectral Plots**
The output frequency spectrum is shown for input frequencies of 406kHz, 4.9MHz and 7.2MHz. All of these plots were generated with a 15MSPS Clock. Four thousand point (4K) FFT’s were taken, using a Blackmann-Harris window and the power spectra were averaged over 10 cycles to accentuate the harmonics and reduce variance in the noise level. The plots show the frequency spectrum from dc to the 7.5MHz Nyquist frequency for 15MSPS.

**SFSR and SNR vs Input level Plots**
As the signal level is reduced from full scale, the noise level remains relatively constant. This results in a backward declining straight line shown as SNR vs Input Amplitude. In some converters the ‘noise’ is not independent of the input signal level and hence the line may not be straight. The 74dB theoretical limit on SNR is shown with the -1dB/dB backward declining slope for reference. The CLC935 noise performance parallels this reference, and indicates that noise performance is relatively uniform for all analog input levels.

The SFSR performance is somewhat less uniform. As the ratio of the largest non-fundamental frequency component relative to the fundamental, it is more susceptible to random variations in the spectrum. The input power was measured at the A/D converter. For each amplitude a 4K point FFT was taken and analyzed to determine the SNR and SFSR. The vertical scale is measured in dB, this is dB relative to the test signal, and the horizontal scale is dB-FS which is dB relative to the converter’s full-scale analog input range.

**Two Tone Linearity Spectrum**
In a linear system, the input signal can be viewed mathematically as a superposition of sinusoids (Fourier Transform). The system output can be predicted by the superpositioning of the individual effects on each of the sinusoid inputs. For example, if a linear network is presented with a single tone signal \( F_1 \), and the result is an attenuation by a factor \( A_1 \), and it is then presented with another frequency \( F_2 \) attenuated by \( A_2 \) through the system, then the expected output for an input of \( F_1 + F_2 \) would be \( A_1 F_1 + A_2 F_2 \).

If the network is not linear, the output will contain frequency components in addition to those present at the input. The most common frequencies likely to be present in the output are at \( MF_1 \pm NF_2 \), where \( M \) and \( N \) are integers, and \( F_1 \) and \( F_2 \) are the two input frequencies. In the two-tone linearity plot, the input to the CLC935 consists of 4.95MHz and 5.05MHz superpositioned sinusoids. Intermodulation terms on the order of -80dBc confirm the CLC935’s excellent linearity.

**SNR, and SFSR vs Input Frequency**
These plots show the variation in converter performance relative to analog input frequency. Input frequencies to about 65MHz (the Full-Power-Bandwidth) are included, and should be useful for over-sampling applications. Beyond the full-power bandwidth, performance for large signals degrades quickly. The small-signal-bandwidth (measured with analog inputs below 200mVpp) performance does not degrade until around 135MHz.

**SNR vs Conversion Rate**
There are several critical timing processes inside the converter, including the track time, the time allowed for settling of internal nodes, and time to perform the coarse and fine quantizations. When a rising edge of CONVERT is detected, a pre-timed sequence of events is set into motion. Accordingly the performance of the CLC935 is very independent of clock rate, up to the specified speed of 15MSPS, after which performance can degrade rapidly. If a higher speed conversion is required, the CLC936, 12-bit 20MSPS A/D converter is recommended. The CLC936 is pin compatible with the CLC935, providing an easy upgrade path.

**Digital output skew plot**
The digital outputs make their transition \( T_{\text{ops}} \)ns after the rising edge of the CONVERT signal. The actual time to this transition varies slightly from output bit to output bit. The amount of this variation is small, and well within the timing needs for this type of system. In the Bit Skew plot, all 12 output bits are shown for various transitions. As can be seen, the total variation, bit-to-bit, is about 2ns.

**Pulse response plots**
This plot has been generated with a 1Vpp flat top pulse input signal with a 600ps rise time and a 15.000549MHz repetition rate. The input signal is effectively aliased to 549Hz when sampled at 15MSPS.

A sequence of 4096 samples will now represent an equivalent time window of 10ns. Any slew rate limitations, ringing or other non-idealities in the A/D analog input stage will now be apparent in the aliased output signal. As can be seen from the plots, the only non-ideality is a bandwidth limitation, which limits the time to an accurate sample to about 7ns. If your input signal is a step function, such as a CCD output or T/H output, this means that the sample should be taken at least 7ns after the start of the transition.

### Pin Description and Usage

**ECL-Level Digital Inputs**

CONVERT, CONVERT

*Differential Convert Command* initiates a new conversion cycle on the rising edge of CONVERT.

DATA INV

DATA INVERT is an active HIGH (grounded) ECL input which causes the data outputs [D2 to (LSB) D12] to be inverted. In normal operation, DATA INV is left floating or tied to ECL logic LOW.

**ECL-Level Digital Outputs**

(DMSB) D1-D12

Digital Data Outputs. D1 is the MSB; D12 is the LSB. In their normal state, the digital outputs offer Inverted version of the MSB, used for 2's Complement coding.

(BOARD) D1

Analog Input

V<sub>IN</sub>

Analog input with a 2V<sub>pp</sub> input range from +1V to -1V.

Gain Adjust

The GAIN ADJUST has a +4V to +1V input range and scales the analog input full-scale range by -10% to +10% respectively. If unused, Gain Adjust should be left floating.

Offset Adjust

The OFFSET ADJUST has a GROUND to OFFSET REFERENCE input range and scales the analog input offset by ±0.1V. If unused, Offset Adjust should be left floating.

Offset Reference

The OFFSET REFERENCE tracks gain adjustments and is used for offset voltage adjust.

**Miscellaneous**

V<sub>REF</sub>

V<sub>REF</sub> is a highly stable +2.500V voltage reference. (Recommended current drain ≤2mA.)

D.N.C

Do Not Connect.

DNC (T/H Output)

Internal Track-and-Hold output voltage test point. Do Not Connect.

**Power and Ground**

+5V, PIns 2, 26; +15V, Pin 34; -5.2V, PIns 3, 22, 27, 31; -15V, Pin 32; GROUND, Pins 1, 21, 30, 38, 40.
In high-speed data acquisition systems, overall performance is usually determined by the A/D converter. Accordingly, special attention should be given to the converter, its operation, and its environment. To assist in this process, information on these critical items has been included in this data sheet. Additional information on using high-performance A/D converters can also be found in Comlinear Corporation application note AD-01.

Principle of Operation
The CLC935 is a complete two step, subranging A/D converter, with input buffering, internal track-and-hold, quantizer, and all necessary voltage references. The block diagram for the converter is shown below.

The conversion cycle is initiated on the rising edge of the CONV signal. The analog input is sampled by the track-and-hold amplifier and is then digitized with an 8-bit digitizer. The 6 MSBs of this conversion are the "coarse-quantization", which drive a 14-bit accurate DAC to match the input level. The DAC output is then subtracted from the original analog input to generate an error signal, which is then digitized. The two digitized results are combined to form the 12-Bit accurate output. Error correction and output buffering are also provided by the CLC935.

Analog Input Driving Circuits
The high dynamic range of the CLC935 places high demands on any analog processing circuitry that precedes the converter. This is particularly true in the area of harmonic distortion where the CLC935’s performance often exceeds -77dBc. Fortunately the CLC935 employs an internal buffer for the analog input, and external buffering circuits are usually not required. Both the CLC207 and the CLC409 amplifiers can be configured for better than -80dBc harmonic distortion (note that the CLC409 does not support 12-bit settling performance necessary for "time domain" applications). This makes them ideal choices for any analog signal conditioning or buffering that may be required.

Gain Adjust
The CLC935 input range can be adjusted ±10% from its nominal ±1V range. The input range is controlled by adjusting the gain of the internal input buffer. This gain is controlled by the applied voltage at the GAIN ADJUST (pin33). The relationship between applied voltage at pin 33 and the analog input range is:

\[ \text{analog input range} = \pm [2V + (0.129)(V_{\text{GAIN ADJUST}} - 2.5V)] \]

</tr>
</tbody>
</table>

Analog Input Range Adjust Circuit
A resistor from GAIN ADJUST to ground provides a second method of adjusting the analog input range. This technique will decrease the converter's gain and increase the analog input range.

\[ R = \frac{774}{A - 4800} \]

Where \( A \) is the gain change factor, i.e., 0.01 equals 1% change.

Analog Input Buffering
The CLC935 input range can be adjusted ±10% from its nominal ±1V range. The input range is controlled by adjusting the gain of the internal input buffer. This gain is controlled by the applied voltage at the GAIN ADJUST (pin33). The relationship between applied voltage at pin 33 and the analog input range is:

\[ \text{analog input range} = \pm [2V + (0.129)(V_{\text{GAIN ADJUST}} - 2.5V)] \]

Analog Input Range Adjust Circuit
A resistor from GAIN ADJUST to ground provides a second method of adjusting the analog input range. This technique will decrease the converter's gain and increase the analog input range.

\[ R = \frac{774}{A - 4800} \]

Where \( A \) is the gain change factor, i.e., 0.01 equals 1% change.

Alternate Input Range Adjust Circuit
Offset Adjust
Typically the center of the ±1V analog input range is laser trimmed to 0V during construction. By applying a voltage at the OFFSET ADJUST (pin 36), the analog input offset can be adjusted approximately ±100mV around ground. The applied voltage at pin 36 can range from GROUND to V_OFFSET REFERENCE. If the OFFSET REFERENCE (pin 37) voltage is used to generate the applied OFFSET ADJUST voltage, adjustments in the analog input range offset will track any adjustments made to the analog input range. Analog input range gain and offset adjustments are tightly coupled when the OFFSET REFERENCE is used to generate the OFFSET ADJUST applied voltage. Self-calibration techniques for adjusting offset and gain should use OFFSET REFERENCE in adjusting the offset.

Analog input offset and gain adjustments can be made independent of each other if the V_REF_OUT (pin 35) is used to generate the applied OFFSET ADJUST voltage instead of the OFFSET REFERENCE voltage. If the V_REF_OUT approach is adopted, the CLC935 offset and gain will be independent of each other, but will likely need an iterative adjustment approach where both offset and gain are successively adjusted until the desired result is obtained.
Offset Adjust Range  |  Analog Input Offset
---|---
V OFFSET REFERENCE pin (36) | +100mV
open | 0mV
GROUND | -100mV

Offset Adjust Circuit

The OFFSET ADJUST and GAIN ADJUST pins are very sensitive to noise; and should be bypassed to ground with 0.1μF ceramic capacitors. If the OFFSET ADJUST and GAIN ADJUST pins are not used, then they should be left floating.

CONVERT Clock Generation

All high-speed high-resolution A/D converters are sensitive to the CONVERT clock quality. With a full scale 7MHz analog input signal, the slew rate at the 0V crossing is 90LSB/ns. An error (jitter) of as little as 5ps in the clock edge will yield a 0.5LSB error at the A/D output. This is as great or greater than any other error source likely to be present. This type of clock error or clock jitter is most easily seen in the form of poor SNR (signal-to-noise ratio). If the SNR is below expectations, clock jitter should be investigated.

\[
SNR_{\text{MAX}} = 20 \log \left[ \frac{1}{2\pi f_{\text{in}} \text{Jitter}_{\text{RMS}}} \right]
\]

where ...

\[
\text{Jitter}_{\text{RMS}} = \sqrt{(\text{clock jitter}_{\text{RMS}})^2 + (\text{analog jitter}_{\text{RMS}})^2}
\]

It should also be noted that jitter in the analog input source will have the same detrimental effect on SNR. Analog input signal jitter is usually only a problem in evaluation setups, and does not generally present a problem in full systems.

Low-jitter crystal controlled oscillators make the best CONVERT clock sources. If the CONVERT clock is generated from another type of source, by gating, dividing or other method, it should be registered by the original clock as the last step. This should keep jitter terms from compounding.

For variable frequency CONVERT clocks, low-phase-noise frequency synthesizers like the Fluke 6080A or the HP6662 are good choices. Sinusoidal sources of this type will require a sine-to-ECL conversion circuit, such as the one above. This circuit operates consistently with low level inputs (0dBm), but is sensitive to noise (jitter) from the synthesizer. By maintaining a larger input level (+6dBm), the 10114 jitter contribution can be greatly minimized.

Output Coding

The CLC935 is capable of producing four possible digital output formats: offset binary, two’s complement, and their inverted versions. In offset binary the outputs count from 000h to 0FFFFh, as the input varies from -FS (full-scale) to +FS. For two’s complement output coding, the MSB in the offset binary format is inverted. On the CLC935, this is achieved by using the D1 (MSB) (pin 6) output rather than the D1 (MSB) (pin 7). When using inverted coding formats, the data outputs D2 - D12 (LSB) are inverted by tying DATA INV (pin 25) to an ECL logic HIGH (or grounding). For non-inverted operation DATA INV should be left floating, or tied to an ECL logic LOW.

Output Data and "Data Ready"

The CLC935 has one internal pipeline delay. This means that a sample taken on the rising edge of CONVERT (tN) will appear at the output on the tN + tDV clock cycle. The internally latched data from the previous conversion (tN) is latched to the digital outputs on the rising edge of CONVERT. The previous output data is guaranteed to be valid for at least tRD after the rising edge of CONVERT and the new output data will be stable tDV after the rising edge of CONVERT (see timing diagram).

Since the CLC935 has a synchronous interface, it does not require a separate Data Ready signal. The falling edge of the CONVERT should be used to generate the output latch clock signal, or Data Ready signal, as required by the system. This will limit the bulk of the digital switching noise to a period well away from the sensitive analog processing inside the converter. The use of the rising edge of CONVERT for Data Ready, and buffer clocking signals, is not recommended. Separate drivers for CONVERT and output latch strobing should be used to minimize corruption and jitter in the CONVERT signal.

Digital Interface and Termination Differences

All high-resolution A/D converters are susceptible to performance degradation if interference from the digital outputs is allowed to couple back to the analog input. Capacitive coupling back to the A/D input can result in increased harmonic distortion, or an elevated noise floor. This "noise" tends to be highly correlated to the input signal, and is difficult to remove through standard DSP noise reduction techniques. To minimize this effect, the CLC935 employs ECL "compatible" outputs rather than larger swing TTL compatible outputs. Additional measures to reduce output-to-input coupling have resulted in some slight differences when interfacing to the CLC935 as compared with true ECL.
The most significant difference is that the CLC935 does not require standard ECL output terminations. Most ECL circuits require a 50Ω terminating resistor from each output to a -2.0V bias supply (this can be implemented with a Thevenin equivalent resistor network between ground and the -5.2V supply). These terminations, when coupled with very low ECL output impedance, allow transmission lines to be driven at very high speeds. Unfortunately, typical ECL output terminations tend to dissipate an appreciable amount of dc power while also creating significant ground currents during switching. A typical Thevenin equivalent termination consumes an average current of 25mA. This yields 130mW per termination, which when multiplied by the 12 bits results in more than 1.5W being devoted to the terminations alone.

**CLC935 Internal ECL Termination Circuit**

The CLC935 outputs are 10KH ECL logic compatible with internal constant-current pull-downs, and are designed to be connected directly to 10KH level inputs with no external termination. The power dissipation in each termination is the 6mA standing current, multiplied by the 5.2V supply, or 31mW per output. For a 12-bit converter, this represents 375mW. When compared to external Thevenin terminations, the power savings is 1.2W.

**Output Latching and Level Translation**

Parasitic capacitances and inductances should be minimized, when interfacing to the 935 outputs. Output latches (10176) or buffers should be placed as close as practical to the output pins. If these output latches drive a significant trace load on the same board as the converter, differential output latches (10E151) and trace routing should be used.

In many systems, DSP and other forms of processing will employ TTL or CMOS circuitry. The output logic levels of the CLC935 will need to be translated to match those of the processing circuitry. Several options and translators exist to perform this task. Special care must be used if "10125" type circuits are used since these devices are not particularly suited to a high-resolution, low-noise, analog environment. Other options include the 105574.

**ECL to TTL/CMOS Level Translator Options**

**Power supplies, Grounding, and Bypassing**

To obtain the best possible performance from any high-speed device, the design engineer must pay close attention to power supplies, grounding and bypassing. This applies not only to the A/D converter itself but throughout the system as well.

The recommended supply decoupling scheme is as follows: One 0.01µF to 0.033µF chip capacitor at every supply pin, with a +6.8µF to +10µF tantalum for each of the four main supplies feeds (within a few inches of the ADC). Note that supply feeds with excessive digital switching noise may require separate filtering using ferrite beads, additional capacitance, or split supplies. Proper bypassing of all other integrated circuits, especially logic circuits, should minimize power supply and ground transients.

All of the CLC935 grounds are internally connected. A single low-impedance ground plane is recommended for the CLC935. Split analog and digital grounds are not recommended for the CLC935. The SIGNAL GND is used internally for the track-and-hold and buffering amplifiers, while the other GROUND pins are essentially power supply returns.

The SIGNAL GND pins (pins 39 & 40) are very sensitive nodes, and should have a solid, low-impedance, ground connection. The path that the input signal and its return currents follow must be isolated from other circuitry. Single-point grounding at the converter should minimize common impedance paths which would allow other signals to directly couple into the analog input, affecting accuracy.

**Recommended Output Buffering Circuits**
Thermal Considerations
The CLC935 dissipates approximately 5.2W. The following strategies can be applied to minimize junction temperatures:

a) A thick copper ground plane ... an appreciable amount of heat is conducted out of the A/D through its leads.

b) A copper or aluminum stand-off between the ground plane and the bottom of the CLC935 package (thermal paste may be useful).

c) A SIL PAD\(^2\) between the ground plane and the bottom of the CLC935 package. To maximize heat conduction leave a patch of exposed (no solder mask) ground plane under the CLC935.

d) Moving air over the A/D converter.

Evaluation Board and Printed Circuit Board Layout
The keys to a successful CLC935 layout are a substantial low-impedance ground plane, short connections (in and out of the converter), and proper power supply decoupling. The use of a socket for the CLC935 is specifically not recommended in the final system design.

The CONVERT clock line traces should be equal length. If they are not equal, the edges may not arrive at the A/D at the same time, which may allow the clock signals to more easily couple into the analog input.

An evaluation board is available for the CLC935 (assembled - "E935PCASM", or bare board - "730025"). The evaluation board can be used to quickly evaluate the performance of the CLC935. Use of the evaluation board as a model is highly recommended.

Applications Support
Comlinear Corporation maintains a staff of applications engineers who are available for design and applications assistance. They can be reached at (303) 226 0500.

Recommended Power Supply Decoupling Scheme

Complete System Circuit
APPLICATIONS:
• radar processing
• infrared processing/electronic imaging
• instrumentation
• medical imaging
• transient-signal recorders

DESCRIPTION:
The CLC936 is a 12-bit analog-to-digital converter hybrid, including voltage references, track-and-hold, and 12-bit quantizer with ECL compatible outputs. The CLC936 has been especially optimized for a Spurious-Free-Signal-Range of better than 70dB. The CLC936 is constructed using advanced thin-film hybrid technology in a fully certified MIL-STD-1772 facility.

Comprehensive dynamic testing on every part ensures that system performance goals will be met, including spurious-free-signal-range (SFSR) of 73dB@407kHz and 65dB@9.68MHz. This, coupled with an SNR specification of 64dB@9.68MHz, means that the CLC936 is ideally suited for use in areas such as radar and instrumentation signal processing.

The CLC936 incorporates a complete two-pass sub-ranging architecture, constructed from several high-speed building blocks. A broadband (135MHz) input amplifier buffers input signals and provides an accurate drive signal to the on-board track-and-hold. Laser trimmed gain and offset circuits assure accurate matching unit to unit. The latched outputs of the CLC936 mean that only a convert clock, analog input, and power supplies are required for operation; internal logic generates all required timing signals.

The CLC936AC is specified over a temperature range of 0°C to +70°C, while the CLC936A8C is specified over a range of -55°C to +125°C. Both devices are packaged in 40-pin, 1.1in wide, ceramic DIPs (note: leads are side brazed for easy access and inspection). Contact factory for availability of "gull-wing" surface-mount versions.

FEATURS (typical):
• 71dB spurious free signal range; \( f_{\text{IN}} = 4.97 \text{MHz} \)
• no missing codes guaranteed
• 0.7LSB differential linearity
• small package (2.28in²)

- Supply current (-Vcc = -15.0V) 20MSPS; no load
- Nominal power dissipation

---

**Notes**

1. Parameters preceded by an * are 100% tested. AC units are tested at 25°C and guaranteed at 0°C and 70°C.

2. Absolute maximum ratings are limiting values, to be applied individually, and beyond which the serviceability of the circuit may be impaired. Functional operability under any of these conditions is not necessarily implied. Exposure to maximum ratings for extended periods may affect device reliability.

3. Junction temperature rise above case = 16°C; θj-case=16°C/W; θj-case=7°C/CW@500LFPM. Use of a S-L-PAD® #550007, from Berquist (1-800-347-4572), can lower case-to-ambient rise; θj-case = 12°C/W @ still air, 12in² ground-plane; θj-case = 3.4°C/CW @ 100LFPM, 12in² ground-plane.

4. Planned product improvements are expected to lower -5.2V supply current, as well as nominal power dissipation.

Comlinear reserves the right to change specifications without notice.

**Note:** $t_{DV} = t_{HLD} + Data$ Bit Skew
Analog-to-Digital converters are specified in many ways. As a component achieves higher performance, its specifications and their definitions can become more critical. Fortunately, the vast number of converter applications can generally be placed into one of two classes. These are processed data and non-processed data applications. The distinction seems quite simple but the split implies a completely different approach in specifying A/D converters for a given application.

The processed data area includes the frequency domain applications which employ Fourier processing (FFT). Also in this category are the highly averaged applications, usually concerned with low noise. In each case, the converter’s data is averaged or convolved mathematically. This processing reduces the apparent noise level in the output data. For FFTs, the noise is simply spread over a large number of frequency bins. For simple averaging approaches, the gaussian distribution of noise is greatly reduced, appearing to increase the converter’s resolution. Processed applications include radar, network and spectrum analyzers, communications receivers, etc.

The non-processed applications tend to take the converter’s data in its original form with very little processing. This means that the noise reduction benefits of the processed applications are not seen. The non-processed area is composed primarily of time domain applications like imaging, DSO’s, ultrasound, etc.

The processed vs. non-processed issue has several implications in terms of converter specifications. For the non-processed (time domain) systems the dominant converter specifications deal with noise (SNR) and converter accuracy (DNL). The converter’s quantization noise and input stage noise dominate converter accuracy. The harmonic distortion (primarily INL) of the converter is generally of little interest given that most time domain applications present data for visual analysis and tend to focus on "local" accuracy rather than over the full input range. "Local" accuracy is best described through the standard noise measurements, such as SNR and DNL.

In the frequency domain application areas, the noise of the converter is processed to the point where, for almost all systems, it is no longer of issue. This is manifested as a reduction in the apparent noise floor. The actual RMS noise is not reduced, but is spread over more and more frequency bins as processing levels are increased. Unfortunately, the harmonic distortion performance of the converter is not affected by increased processing. This makes the harmonic performance, or more specifically the spurious performance, the dominant error source for frequency domain applications. SFSR becomes the dominant specification for determining converter performance in the frequency domain.

Signal-to-Noise Ratio (SNR) is the ratio of the power contained in the fundamental signal compared to the power contained in the entire noise floor. That is to say all individual noise components are added together to arrive at an integrated noise power. For SNR, harmonic power is excluded from the noise measurement. SNR is particularly important in time domain applications like digital image processing and infrared imaging, where conversion accuracy can be heavily degraded by integrated noise.

Signal-to-Noise-and-Distortion (SINAD) is the ratio of the fundamental signal power to the power at all other frequencies. This includes all noise as well as all harmonics. SINAD is a worst case specification for A/D converters, combining variables from both frequency and time domains. The value of SINAD in high-performance converter applications is not clear since it does not accurately predict the best converter for a given application. Because applications tend to fall into time domain/non-processed or frequency domain/processed applications, those specifications more directly related to the application should be the primary focus in selecting the converter.

Total Harmonic Distortion (THD) is the combined power of a specified number of harmonics, compared to the power of the fundamental signal. Harmonics are located at predictable frequencies, spaced at integer multiples of the fundamental signal. For example, a 1MHz fundamental would generate harmonics at 2MHz, 3MHz, 4MHz, ..., and so on. In practice, only the first five harmonics contribute significantly to THD, although more may be included in the measurement. THD does not tend to apply well in frequency domain applications which are by their nature very SFSR oriented. In time domain applications, THD is indicative of full-scale input range distortion, however the high-performance time domain applications are generally most interested in local distortion performance. Local distortion and accuracy is dominated by DNL. The use of THD for applications requiring local performance is not likely to yield accurate or repeatable results in selecting the correct converter.

Spurious-Free-Signal-Range (SFSR) is the “clean” dynamic range of the converter, free from harmonic and spurious signals. SFSR is ratio of the power of the fundamental compared to the power of the next largest component in the frequency spectrum. The SFSR specification is especially important to frequency domain applications which perform Fourier transforms to analyze the converter’s output data. Processed applications like radar and network analyzers are typical areas where SFSR offers a direct prediction of converter’s performance at both the system and component levels. SFSR is the single best specification for selecting a converter to be used in a frequency domain application.

In-Band Harmonics (IBH) is the ratio of the power of the fundamental compared to the power of the single largest harmonic. This specification is very similar to SFSR, but since it only considers a fairly limited number of harmonics, it is potentially an incomplete gauge of converter performance. SFSR is more stringent and should be used whenever possible in lieu of IBH.

**Typical Frequency Spectrum and its Components**

![Typical Frequency Spectrum and its Components](image_url)
Spectral Plots
The output frequency spectrum is shown for input frequencies of 404KHz, 1.85MHz, 4.978MHz and 9.685MHz. All of these plots were generated with a 20MSPS Clock. Four thousand point (4K) FFT’s were taken, using a Blackmann-Harris window and the power spectra were averaged over 10 cycles to accentuate the harmonics and reduce variance in the noise level. The plots show the frequency spectrum from dc to the 10MHz Nyquist frequency for 20MSPS.

SFSR and SNR vs Input level Plots
As the signal level is reduced from full scale, the noise level remains relatively constant. This results in a backward declining straight line shown as SNR vs Input Amplitude. In some converters the ‘noise’ is not independent of the input signal level and hence the line may not be straight. The 74dB theoretical limit on SNR is shown with the -1dB/dB backward declining slope for reference. The CLC936 noise performance parallels this reference, and indicates that noise performance is relatively uniform for all analog input levels.

The SFSR performance is somewhat less uniform. As the ratio of the largest non-fundamental frequency component relative to the fundamental, it is more susceptible to random variations in the spectrum. The input power was measured at the A/D converter. For each amplitude a 4K point FFT was taken and analyzed to determine the SNR and SFSR. The vertical scale is measured in dBc, this is dB relative to the test signal, and the horizontal scale is dB-FS which is dB relative to the converter’s full-scale analog input range.

Two Tone Linearity Spectrum
In a linear system, the input signal can be viewed mathematically as a superposition of sinusoids (Fourier Transform). The system output can be predicted by the superpositioning of the individual effects on each of the sinusoid inputs. For example, if a linear network is presented with a single tone signal \( F_1 \), and the result is an attenuation by a factor \( A_1 \), and it is then presented with another frequency \( F_2 \) attenuated by \( A_2 \) through the system, then the expected output for an input of \( F_1 + F_2 \) would be \( A_1 F_1 + A_2 F_2 \).

If the network is not linear, the output will contain frequency components in addition to those present at the input. The most common frequencies likely to be present in the output are at \( MF_1, \pm NF_2, \) where \( M \) and \( N \) are integers, and \( F_1 \) and \( F_2 \) are the two input frequencies. In the two-tone linearity plot, the input to the CLC936 consists of 4.95MHz and 5.05MHz superpositioned sinusoids. Intermodulation terms on the order of -80dBc confirm the CLC936’s excellent linearity.

SNR, and SFSR vs Input Frequency
These plots shows the variation in converter performance relative to analog input frequency. Input frequencies to about 65MHz (the Full-Power-Bandwidth) are included, and should be useful for over-sampling applications. Beyond the full-power-bandwidth, performance for large signals degrades quickly. The small-signal-bandwidth (measured with analog inputs below 200mVpp) performance does not degrade until around 135MHz.

SFSR vs Conversion Rate
There are several critical timing processes inside the converter, including the track time, the time allowed for settling of internal nodes, and time to perform the coarse and fine quantizations. When a rising edge of CONVERT is detected, a pre-timed sequence of events is set into motion. Accordingly the performance of the CLC936 is very independent of clock rate, up to the specified speed of 20MSPS, after which performance can degrade rapidly.

Digital output skew plot
The digital outputs make their transition \( T_{CU} \) ns after the rising edge of the CONVERT signal. The actual time to this transition varies slightly from output bit to output bit. The amount of this variation is small, and is well within the timing needs for this type of system. In the Bit Skew plot, all 12 output bits are shown for various transitions. As can be seen, the total variation, bit-to-bit, is about 2ns.

Pulse response plots
This plot has been generated with a 1Vpp flat top pulse input signal with a 600ps rise time and a 20.000549MHz repetition rate. The input signal is effectively aliased to 549Hz when sampled at 20MSPS.

A sequence of 4096 samples will now represent an equivalent time window of 10ns. Any slew rate limitations, ringing or other non-idealities in the A/D analog input stage will now be apparent in the aliased output signal. As can be seen from the plots, the only non-ideality is a bandwidth limitation, which limits the time to an accurate sample to about 7ns. If your input signal is a step function, such as a CCD output or T/H output, this means that the sample should be taken at least 7ns after the start of the transition.
Typical Performance Characteristics (T; = +35°C, 20MSPS unless specified)

SFSR & SNR vs. Analog Input Amplitude

- Analog Input (dB below Full Scale)
- SFSR (dB) and SNR (dB)

- FS - 1dB

9.685MHz Output Spectrum

- Frequency 7.5MHz
- 20MSPS
- FS - 1dB
ECL-Level Digital Inputs
CONVERT, CONVERT
"Differential Convert Command" initiates a new conversion cycle on the rising edge of CONVERT.

DATA INV
DATA INVERT is an active HIGH (grounded) ECL input which causes the data outputs [D2 to (LSB) D12] to be inverted. In normal operation, DATA INV is left floating or tied to ECL logic LOW.

ECL-Level Digital Outputs
(MSB) D1-D12
Digital Data Outputs. D1 is the MSB; D12 is the LSB. In their normal state, the digital outputs offer Offset Binary output coding.

(MSB) D1
Inverted version of the MSB, used for 2's Complement coding.

Analog Input
V_IN
Analog input with a 2Vpp input range from +1V to -1V.

Gain Adjust
The GAIN ADJUST has a +4V to +1V input range and scales the analog input full-scale range by -10% to +10% respectively. If unused, Gain Adjust should be left floating.

Offset Adjust
The OFFSET ADJUST has a GROUND to OFFSET REFERENCE input range and scales the analog input offset by ±0.1V. If unused, Offset Adjust should be left floating.

Offset Reference
The OFFSET REFERENCE tracks gain adjustments and is used for offset voltage adjust.

Miscellaneous
V_REF
V_REF is a highly stable +2.500V voltage reference. (Recommended current drain ≤2mA.)

DNC
Do Not Connect.

DNC (T/H Output)
Internal Track-and-Hold output voltage test point. Do not Connect.

Power and Ground
+5V, Pins 2,26; +15V, Pin 34; -5.2V, Pins 3, 22, 27, 31; -15V, Pin 32; GROUND, Pins 1, 21, 30, 38, 40.
In high-speed data acquisition systems, overall performance is usually determined by the A/D converter. Accordingly, special attention should be given to the converter, its operation, and its environment. To assist in this process, information on these critical items has been included in this data sheet. Additional information on using high-performance A/D converters can also be found in Comlinear Corporation application note AD-01.

**Principle of Operation**

The CLC936 is a complete two step, subranging A/D converter, with input buffering, internal track-and-hold, quantizer, and all necessary voltage references. The block diagram for the converter is shown below.

**CLC936 Functional Block Diagram**

The conversion cycle is initiated on the rising edge of the CONVERT signal. The analog input is sampled by the track-and-hold amplifier and is then digitized with an 8-bit digitizer. The 6 MSBs of this conversion are the "coarse-quantization", which drive a 14-bit accurate DAC to match the input level. The DAC output is then subtracted from the original analog input to generate an error signal, which is then digitized. The two digitized results are combined to form the 12-Bit accurate output. Error correction and output buffering are also provided by the CLC936.

**Analog Input Driving Circuits**

The high dynamic range of the CLC936 places high demands on any analog processing circuitry that precedes the converter. This is particularly true in the area of harmonic distortion where the CLC936's performance often exceeds -72dBc. Fortunately the CLC936 employs an internal buffer for the analog input, and external buffering circuits are usually not required. Both the CLC207 and the CLC409 amplifiers can be configured for better than -80dBc harmonic distortion (note that the CLC409 does not support 12-bit settling performance necessary for "time domain" applications). This makes them ideal choices for any analog signal conditioning or buffering that may be required.

**Gain Adjust**

The CLC936 input range can be adjusted ±10% from its nominal ±1V range. The input range is controlled by adjusting the gain of the internal input buffer. This gain is controlled by the applied voltage at the GAIN ADJUST (pin33). The relationship between applied voltage at pin 33 and the analog input range is:

\[
\text{analog input range} = \pm [2V + (0.129)(V_{\text{GAIN ADJUST}} - 2.5V)]
\]

**Analog Input Range Adjust Circuit**

A resistor from GAIN ADJUST to ground provides a second method of adjusting the analog input range. This technique will decrease the converter's gain and increase the analog input range.

\[
R = \frac{2500}{1.8V_{\text{pp}} - 1.0V_{\text{pp}}}
\]

Where \( R \) is the gain change factor, \( A \) 0.01 equals 1% change.

**Alternate Input Range Adjust Circuit**

**Offset Adjust**

Typically the center of the ±1V analog input range is laser trimmed to 0V during construction. By applying a voltage at the OFFSET ADJUST (pin 36), the analog input offset can be adjusted approximately ±100mV around ground. The applied voltage at pin 36 can range from GROUND to \( V_{\text{OFFSET REFERENCE}} \). If the OFFSET REFERENCE (pin 37) voltage is used to generate the applied OFFSET ADJUST voltage, adjustments in the analog input range offset will track any adjustments made to the analog input range gain. Analog input range gain and offset adjustments are tightly coupled when the OFFSET REFERENCE is used to generate the OFFSET ADJUST applied voltage. Self-calibration techniques for adjusting offset and gain should use OFFSET REFERENCE in adjusting the offset.

Analog input offset and gain adjustments can be made independent of each other if the \( V_{\text{REF OUT}} \) (pin 35) is used to generate the applied OFFSET ADJUST voltage instead of the OFFSET REFERENCE voltage. If the \( V_{\text{REF OUT}} \) approach is adopted, the CLC936 offset and gain will be independent of each other, but will likely need an iterative adjustment approach where both offset and gain are successively adjusted until the desired result is obtained.
The type of source, by gating, dividing or other method, it the specific GAIN adjust voltage at pin 33. All sources have the same detrimental effect on jitter terms from compounding. However, in high-speed high-resolution converters are sensitive to the CONVERT clock quality. With a full scale 7MHz analog input signal, the slew rate at the 0V crossing is 90LSB/ns. An error (jitter) of as little as 5ps in the clock edge will yield a 0.5LSB error at the A/D output. This is as great or greater than any other error source likely to be present. This type of clock error or clock jitter is most easily seen in the form of poor SNR (signal-to-noise ratio). If the SNR is below expectations, clock jitter should be investigated.

$$\text{SNR}_{\text{MAX}} = 20 \log \left(\frac{1}{2\pi f_0 \cdot \text{jitter}_{\text{RMS}}}\right)$$

where ...

$$\text{jitter}_{\text{RMS}} = \sqrt{\text{clock jitter}_{\text{RMS}}^2 + \text{analog jitter}_{\text{RMS}}^2}$$

It should also be noted that jitter in the analog input source will have the same detrimental effect on SNR. Analog input signal jitter is usually only a problem in evaluation setups, and does not generally present a problem in full systems.

Low-jitter crystal controlled oscillators make the best CONVERT clock sources. If the CONVERT clock is generated from another type of source, by gating, dividing or other method, it should be registered by the original clock as the last step. This should keep jitter terms from compounding.

For variable frequency CONVERT clocks, low-phase-noise frequency synthesizers like the Fluke 6080A or the HP8662 are good choices. Sinusoidal sources of this type will require a sine-to-ECL conversion circuit, such as the one above. This circuit operates consistently with low level inputs (0dBm), but is sensitive to noise (jitter) from the synthesizer. By maintaining a larger input level (>-6dBm), the 10114 jitter contribution can be greatly minimized.

**Output Coding**

The CLC936 is capable of producing four possible digital output formats: offset binary, two’s complement, and their inverted versions. In offset binary the outputs count from 000h to FFFh, as the input varies from -FS (full-scale) to +FS. For two’s complement output coding, the MSB in the offset binary format is inverted. On the CLC936, this is achieved by using the D1 (MSB) (pin 6) output rather than the D11 (LSB) (pin 7). When using inverted coding formats, the data outputs D2 - D12 (LSB) are inverted by tying DATA IN (pin 25) to an ECL logic HIGH (or grounding). For non-inverted operation DATA INV should be left floating, or tied to an ECL logic LOW.

**Output Data and "Data Ready"**

The CLC936 has one internal pipeline delay. This means that a sample taken on the rising edge of CONVERT (t\text{R}) will appear at the output on the t\text{R} clock cycle. The internally latched data from the previous conversion (t\text{L}) is latched to the digital outputs on the rising edge of CONVERT. The previous output data is guaranteed to be valid for at least t\text{L+D} after the rising edge of CONVERT and the new output data will be stable t\text{L} after the rising edge of CONVERT (see timing diagram).

Since the CLC936 has a synchronous interface, it does not require a separate Data Ready signal. The falling edge of the CONVERT should be used to generate the output latch clock signal, or Data Ready signal, as required by the system. This will limit the bulk of the digital switching noise to a period well away from the sensitive analog processing inside the converter. The use of the rising edge of CONVERT for Data Ready, and buffer clocking signals, is not recommended. Separate drivers for CONVERT and output latch strobing should be used to minimize corruption and jitter in the CONVERT signal.

**Digital Interface and Termination Differences**

All high-resolution A/D converters are susceptible to performance degradation if interference from the digital outputs is allowed to couple back to the analog input. Capacitive coupling back to the A/D input can result in increased harmonic distortion, or an elevated noise floor. This "noise" tends to be highly correlated to the input signal, and is difficult to remove through standard DSP noise reduction techniques. To minimize this effect, the CLC936 employs ECL "compatible" outputs rather than larger swing TTL compatible outputs. Additional measures to reduce output-to-input coupling have resulted in some slight differences when interfacing to the CLC936 as compared with true ECL.
The most significant difference is that the CLC936 does not require standard ECL output terminations. Most ECL circuits require a 50Ω terminating resistor from each output to a -2.0V bias supply (this can be implemented with a Thevenin equivalent resistor network between ground and the -5.2V supply). These terminations, when coupled with very low ECL output impedance, allow transmission lines to be driven at very high speeds. Unfortunately, typical ECL output terminations tend to dissipate an appreciable amount of dc power while also creating significant ground currents during switching. A typical Thevenin equivalent termination consumes an average current of 25mA. This yields 130mW per termination, which when multiplied by the 12 bits results in more than 1.5W being devoted to the terminations alone.

**CLC936 Internal ECL Termination Circuit**

The CLC936 outputs are 10KH ECL logic compatible with internal constant-current pull-downs, and are designed to be connected directly to 10KH level inputs with no external termination. The power dissipation in each termination is the 6mA standing current, multiplied by the 5.2V supply, or 31mW per output. For a 12-bit converter, this represents 375mW. When compared to external Thevenin terminations, the power savings is 1.2W.

**Output Latching and Level Translation**

Parasitic capacitances and inductances should be minimized, when interfacing to the 936 outputs. Output latches (10176) or buffers should be placed as close as practical to the output pins. If these output latches drive a significant trace load on the same board as the converter, differential output latches (10E151) and trace routing should be used.

In many systems, DSP and other forms of processing will employ TTL or CMOS circuitry. The output logic levels of the CLC936 will need to be translated to match those of the processing circuitry. Several options and translators exist to perform this task. Special care must be used if “10125” type circuits are used since these devices are not particularly suited to a high-resolution, low-noise, analog environment. Other options include the 105574.

**ECL to TTL/CMOS Level Translator Options**

**Power supplies, Grounding, and Bypassing**

To obtain the best possible performance from any high-speed device, the design engineer must pay close attention to power supplies, grounding and bypassing. This applies not only to the A/D converter itself but throughout the system as well.

The recommended supply decoupling scheme is as follows: One 0.01μF to 0.033μF chip capacitor at every supply pin, with a +6.8μF to +10μF tantalum for each of the four main supplies feeds (within a few inches of the ADC). Note that supply feeds with excessive digital switching noise may require separate filtering using ferrite beads, additional capacitance, or split supplies. Proper bypassing of all other integrated circuits, especially logic circuits, should minimize power supply and ground transients.

All of the CLC936 grounds are internally connected. A single low-impedance ground plane is recommended for the CLC936. Split analog and digital grounds are not recommended for the CLC936. The SIGNAL GND is used internally for the track-and-hold and buffering amplifiers, while the other GROUND pins are essentially power supply returns.

The SIGNAL GND pins (pins 39 & 40) are very sensitive nodes, and should have a solid, low-impedance, ground connection. The path that the input signal and its return currents follow must be isolated from other circuits. Single-point grounding at the converter should minimize common impedance paths which would allow other signals to directly couple into the analog input, affecting accuracy.

Recommended Output Buffering Circuits
Thermal Considerations
The CLC936 dissipates approximately 5.4W. The following strategies can be applied to minimize junction temperatures:

a) A thick copper ground plane ... an appreciable amount of heat is conducted out of the A/D through its leads.

b) A copper or aluminum stand-off between the ground plane and the bottom of the CLC936 package (thermal paste may be useful).

c) A SIL PAD between the ground plane and the bottom of the CLC936 package. To maximize heat conduction leave a patch of exposed (no solder mask) ground plane under the CLC936.

d) Moving air over the A/D converter.

Evaluation Board and Printed Circuit Board Layout
The keys to a successful CLC936 layout are a substantial low-impedance ground plane, short connections (in and out of the converter), and proper power supply decoupling. The use of a socket for the CLC936 is specifically not recommended in the final system design.

The CONVERT clock line traces should be equal length. If they are not equal, the edges may not arrive at the A/D at the same time, which may allow the clock signals to more easily couple into the analog input.

An evaluation board is available for the CLC936 (assembled - "E935PCASM", or bare board - "730025"). The evaluation board can be used to quickly evaluate the performance of the CLC936. Use of the evaluation board as a model is highly recommended.

Recommended Power Supply Decoupling Scheme

Complete System Circuit
APPLICATIONS:
• radar processing
• FLIR processing/ electronic imaging
• instrumentation
• medical imaging
• transient-signal recorders

DESCRIPTION:
The CLC937 is a 12-bit analog-to-digital converter subsystem, including 12-bit quantizer, internal track-and-hold, references, and ECL compatible digital outputs. The CLC937 has been especially optimized for a Spurious-Free-Signal-Range of better than 70dB. The CLC937 is constructed using advanced thin-film hybrid technology in a fully certified MIL-STD-1772 facility.

Comprehensive dynamic testing on every part insures that system performance goals will be met, including spurious-free-signal-range (SFSR) of 65dB@9.22MHz. This, coupled with an SNR specification of 65dB@9.22MHz, means that the CLC937 is ideally suited for use in areas like radar and instrumentation signal processing.

The CLC937 incorporates a complete two-pass subranging architecture, constructed from several high-speed building blocks. A broadband (150MHz) input amplifier buffers input signals and provides an accurate drive signal to the on-board track-and-hold. Laser trimmed gain and offset assure accurate matching unit to unit. The latched outputs of the CLC937 mean that only a convert clock, analog input, and power supplies are required for operation; internal logic generates all required timing signals.

The CLC937AC is specified over a temperature range of 0°C to +70°C, while the CLC937A8C is specified over a range of -55°C to +125°C. Both devices are packaged in 40-pin, 1.1in wide, ceramic DIPs (note: leads are side brazed for easy access and inspection). Contact factory for availability of "gull-wing" surface-mount versions.

</table>

Available summer of 1993.

Both versions of the CLC937 are manufactured in Comlinear’s MIL-STD-1772 certified facility in Fort Collins, Colorado, U.S.A.

FEATURES (typical):
• 72dB spurious free signal range; \( f_{\text{in}} = 404\text{kHz} \)
• no missing codes guaranteed
• 0.7LSB differential linearity
• small package (2.28in²)

**Note 1:** Absolute maximum ratings are limiting values, to be applied individually, and beyond which the serviceability of the circuit may be impaired. Functional operability under any of these conditions is not necessarily implied. Exposure to maximum ratings for extended periods may affect device reliability.

**Note 2:** Junction temperature rise above case - 16°C; $\theta_{J}=16°C/W; \theta_{JA}=7°C/W@500LFPM$. Use of a SIL-PAD™ #550007, from Berquist (1-800-347-4572), can lower case-to-ambient rise: $\theta_{JA}=12°C/W@still air, 12in² ground-plane; \theta_{JA}=3.4°C/W@100LFPM, 12in² ground-plane.

**Note 3:** Plan product improvements are expected to lower -5.2V supply current by 200mA, and nominal power dissipation by 1W.

Comlinear reserves the right to change specifications without notice.

ECL-Level Digital Inputs
CONVERT, CONVERT

"Differential Convert Command" initiates a new conversion cycle on the rising edge of CONVERT.

DATA INV
Pin 25
DATA INV is an active HIGH (grounded) ECL input which causes the data outputs [D2 to (LSB) D12] to be inverted. In normal operation, DATA INV is left floating or tied to ECL logic LOW.

ECL-Level Digital Outputs
(MSB) D1-D12
Pins 7 to 18
Digital Data Outputs. D1 is the MSB; D12 is the LSB. In their normal state, the digital outputs offer Offset Binary output coding.

(MSB) D1
Pin 6
Inverted version of the MSB, used for 2's Complement coding.

Analog Input
V IN
Pin 39
Analog input with a 2V \text{pp} input range from +1V to -1V.

Gain Adjust
Pin 33
The GAIN ADJUST has a +4V to +1V input range and scales the analog input full-scale range by -10% to +10% respectively. If unused, Gain Adjust should be left floating.

Miscellaneous
V REF (+2.5V)
Pin 35
V REF is a highly stable +2.500V voltage reference. (Recommended current drain ≤2mA.)

D.N.C
Pins 5, 19, 20, 28, 29, 36, 37
Do Not Connect.

DNC (T/H Output)
Pin 4
Internal Track-and-Hold output voltage test point. Do not Connect.

Power and Ground
+5V, Pins 2, 26; +15V, Pin 34; -5.2V, Pins 3, 22, 27, 31; -15V, Pin 32; GROUND, Pins 1, 21, 30, 38, 40.

- digital communications

**DESCRIPTION:**

The CLC950 is a complex monolithic 12-bit analog-to-digital converter subsystem, including 12-bit quantizer, track-and-hold, and on-board reference buffer. The CLC950 outputs are user selectable as either ECL or TTL compatible. The CLC950 has been especially optimized for high-dynamic range, low power operation with spurious performance in the low 70dBc range.

Comprehensive dynamic testing ensures that each part fully meets guaranteed specifications. Judicious power management and state-of-the-art track-and-hold design combine to provide a signal-to-noise ratio of approximately 69dB@10MHz analog input frequency. Spurious-free-dynamic range is approximately 72dBc@10MHz, significantly advancing ADC performance for high-speed monolithic 12-bit converters.

The CLC950 incorporates a proprietary quantizer architecture, which has been designed to minimize comparator count and the associated power dissipation penalty. The quantizer is combined with a high-dynamic range track-and-hold to form the heart of a full ADC sub-system, including necessary drive amplifiers and an on-board voltage reference buffer. Analog input signal, conversion clock, and power are all that are required for CLC950 operation.

The CLC950ACD is specified over the commercial temperature range of 0°C to 70°C, while the CLC950AID/A8D/A8L are extended temperature versions specified from -55°C to +125°C.

**FEATURES (typical):**
- 72dBc spurious free dynamic range
- 69dB signal-to-noise ratio
- monolithic construction
- low power dissipation 1.5W
- complete subsystem design
- ±1V analog input range

Current-Feedback Amplifiers

The use of clever circuit architectures and the development of high-speed complementary BJT processes make it possible to achieve monolithic speeds and bandwidths hitherto available only in hybrid form.

—Sergio Franco, San Francisco State University
1600 Holloway Avenue, San Francisco, CA 94132

In their effort to approximate the ideal op amp, manufacturers must not only maximize the open-loop gain and minimize input-referred errors such as offset voltage, bias current, and noise, but must also ensure adequate bandwidth and settling-time characteristics. Amplifier dynamics are particularly important in applications like high-speed DAC buffers, subranging ADCs, S/H circuits, ATE pin drivers, and video and IF drivers. Moreover, current manipulation is inherently faster than voltage manipulation. The effect of stray inductances in a circuit is usually less severe than that of its stray capacitances, and BJT's can switch currents much more rapidly than voltages. These technological reasons form the basis of emitter-coupled logic, bipolar DACs, current conveyors, and the high-speed amplifier topology known as current-feedback.1

For true current-mode operation, all nodes in the circuit should ideally be kept at fixed voltages to avoid the slowdown effect by their stray capacitances. However, since the output of the amplifier must be a voltage, some form of high-speed voltage-mode operation must also be provided at some point. This is achieved by employing gain configurations that are inherently immune from the Miller effect, such as the common-collector and the cascode configurations, and by driving the nodes with push-pull stages to rapidly charge/discharge their stray capacitances.

To ensure symmetric rise and fall times, the npn and pnp transistors must have comparable characteristics in terms of cutoff frequency f. Traditionally, monolithic npn's have been plagued by much poorer performance characteristics than their npp counterparts. However, the recent development of truly complementary high-speed processes makes it possible to achieve monolithic speeds that were hitherto available only in hybrid form.

The advantages of the current-feedback topology are best appreciated by comparing it against that of the conventional op amp.2,3

©EDN

The Conventional Op Amp

The conventional op amp consists of a high input-impedance differential stage followed by additional gain stages, the last of which is a low output-impedance stage. As shown in the circuit model of Fig. 1a, the op amp transfer characteristic is

$$V_o = a(jf) V_d$$

(1)

where $V_o$ is the output voltage; $V_d = V_p - V_n$ is the differential input voltage; and $a(jf)$, a complex function of frequency $f$, is the open-loop gain.

Connecting an external network as in Fig. 1b creates a feedback path along which a signal in the form of a voltage is derived from the output and applied to the noninverting input. By inspection,

$$V_o = V_i - \frac{R_1}{R_1 + R_2} V_o$$

(2)

Substituting into Eq. (1), collecting, and solving for the ratio $V_o/V_i$ yields the familiar noninverting amplifier transfer characteristic

$$A(jf) \triangleq \frac{V_o}{V_i} = \left( 1 + \frac{R_2}{R_1} \right) \frac{1}{1 + 1/T(jf)}$$

(3)

where $A(jf)$ represents the closed-loop gain, and

$$T(jf) = \frac{a(jf)}{1 + R_2/R_1}$$

(4)

represents the loop gain.
The designation loop gain stems from the fact that if we break the loop as in Fig. 2a and inject a test signal \( V_i \) with \( V_i \) suppressed, the circuit will first attenuate \( V_i \) to produce \( V_n = V_i / (1 + R_2 / R_1) \), and then amplify \( V_n \) to produce \( V_o = -a V_n \). Hence, the gain experienced by a signal in going around the loop is \( V_o / V_i = -a / (1 + R_2 / R_1) \). The negative of this ratio represents the loop gain, \( T = -V_o / V_i \). Hence, Eq. (4).

The loop gain gives a measure of how close \( A \) is to the ideal value \( 1 + R_2 / R_1 \), also called the noise gain of the circuit. By Eq. (3), the larger \( T \), the better. To ensure substantial loop gain over a wide range of closed-loop gains, op amp manufacturers strive to make \( A \) as large as possible. Consequently, \( V_o \) will assume extremely small values since \( V_o = V_i / a \). In the limit \( a \to \infty \), we obtain \( V_o \to 0 \), that is, \( V_n \to V_o \). This forms the basis of the familiar op amp rule: when operated with negative feedback, an op amp will provide whatever output voltage and current are needed to ideally force \( V_n \) to follow \( V_o \).

The rate at which the output changes with time is the slew-rate (SR). This effect stems from the limited ability of the internal circuitry to charge/discharge capacitive loads, especially the compensation capacitor responsible for open-loop bandwidth \( f_A \).

To illustrate, refer to the circuit model of Fig. 3, which is typical of many op amps. The input stage is a transconductance block consisting of differential pair \( Q_1 - Q_2 \) and current mirror \( Q_3 - Q_4 \). The remaining stages are lumped together as an integrator block consisting of an inverting amplifier and the compensation capacitor \( C \). Slew-rate limiting occurs when the transconductance stage is driven into saturation, so that all the current available to charge/discharge \( C \) is the bias current \( I_f \) of this stage. For example, the 741 op amp has \( I_f = 20 \mu A \) and \( C = 30 \text{ pF} \), so that \( \text{SR} = I_f / C = 0.67 \text{ V/\mu s} \). The step magnitude corresponding to the onset of slew-rate limiting is such that \( \Delta V_i / \tau = \text{SR} \), that is, \( \Delta V_i = \text{SR} \times \tau = (0.67 \text{ V/\mu s}) \times (170 \text{ ns}) = 116 \text{ mV} \). As long as the step is less than 116 mV, a 741 voltage follower will respond with an exponential transition governed by \( \tau = 170 \text{ ns} \), whereas for a greater input step the output will slew at a constant rate of 0.67 V/\mu s.
Fig. 3: Simplified slew-rate model of a conventional op amp.

In many applications the dynamic parameter of greatest concern is the **settling time**, that is, the time it takes for the output to settle and remain within a specified band around its final value, usually for a full-scale output transition. Clearly, slew-rate limiting plays an important role in the settling-time characteristic of the device.

### The Current-Feedback Amplifier

As shown in the circuit model of Fig. 4, the architecture of the current-feedback amplifier (CF amp) differs from the conventional op amp in two respects:

1. The input stage is a **unity-gain voltage buffer** connected across the inputs of the op amp. Its function is to force $V_n$ to follow $V_p$, very much like a conventional op amp does via negative feedback. However, because of the low output impedance of this buffer, current can easily flow in or out of the inverting input, though we shall see that in normal operation this current is extremely small.

2. Amplification is provided by a **transimpedance amplifier** which senses the current delivered by the buffer to the external feedback network, and produces an output voltage $V_o$ such that

$$V_o = z(jf)I_n$$  \hspace{1cm} (8)

where $z(jf)$ represents the transimpedance gain of the amplifier, in V/A or Ω, and $I_n$ is the current out of the inverting input.

To fully appreciate the inner workings of the CF amp, it is instructive to examine the simplified circuit diagram of Fig. 5a. The input buffer consists of transistors $Q_1$ through $Q_4$. While $Q_1$ and $Q_2$ form a low-output-impedance push-pull stage, $Q_3$ and $Q_4$ provide $V_{BE}$ compensation for the push-pull pair, as well as a Darlington function to raise the input impedance.

Summing currents at the inverting node yields $I_1 - I_2 = I_n$, where $I_1$ and $I_2$ are the push-pull transistor currents. Two Wilson current mirrors, consisting of transistors $Q_9-Q_{10}-Q_{11}$ and $Q_{13}-Q_{14}-Q_{15}$, reflect these currents and recombine them at a common node, whose equivalent capacitance to ground has been designated as $C$. By mirror action, the current through this capacitance is $I_C = I_1 - I_2$, that is

$$I_C = I_n$$  \hspace{1cm} (9)

The voltage developed by $C$ in response to this current is then conveyed to the output via a second buffer, consisting of $Q_5$ through $Q_6$. The salient features of the CF amp are summarized in block diagram form in Fig. 5b.

When the amplifier loop is closed as in Fig. 4b, and whenever an external signal tries to imbalance the two inputs, the input buffer will begin sourcing (or sinking) an imbalance current $I_n$ to the external resistances. This imbalance is then conveyed by the Wilson mirrors to capacitor $C$, causing $V_o$ to swing in the positive (or negative) direction until the original imbalance $I_n$ is neutralized via the negative feedback loop. Thus, $I_n$ plays the role of error signal in the system.

---

**Fig. 4:** Circuit model of the current-feedback amplifier, and connection as a noninverting amplifier.

**Fig. 5:** Simplified circuit diagram and block diagram of a current-feedback amplifier. (Courtesy of Comlinear Corporation.)
To obtain the closed-loop transfer characteristic, refer again to Fig. 4b. Summing currents at the inverting node yields

\[ I_\text{n} = \frac{V_\text{i}}{R_1} - \frac{V_\text{o} - V_\text{n}}{R_2} \]  

(10)

since the buffer ensures \( V_\text{n} = V_\text{p} = V_\text{i} \) we can rewrite as

\[ I_\text{n} = \frac{V_\text{i}}{R_1 || R_2} - \frac{V_\text{o}}{R_2} \]  

(11)

confirming that the feedback signal \( V_\text{o}/R_2 \) is now in the form of a current. Substituting into Eq. (8), collecting, and solving for the ratio \( V_\text{o}/V_\text{i} \) yields

\[ A(jf) \triangleq \frac{V_\text{o}}{V_\text{i}} = \left( 1 + \frac{R_2}{R_1} \right) \frac{1}{1 + 1/T(jf)} \]  

(12)

where \( A(jf) \) represents the closed-loop gain of the circuit, and

\[ T(jf) = \frac{z(jf)}{R_2} \]  

(13)

represents the loop gain. This designation stems again from the fact that if we break the loop as in Fig. 6a, and inject a test voltage \( V_\text{T} \) with the input \( V_\text{i} \) suppressed, the circuit will first convert \( V_\text{T} \) to the current \( I_\text{n} = -V_\text{T}/R_2 \), and then convert \( I_\text{n} \) to the voltage \( V_\text{o} = zI_\text{n} \), so that \( T \triangleq -(V_\text{o}/V_\text{T}) = z/R_2 \), as expected.

In an effort to ensure substantial loop gain to reduce the closed-loop gain error, manufacturers strive to make \( z \) as large as possible relative to the expected values of \( R_2 \). Consequently, since \( I_\text{n} = V_\text{o}/z \), the inverting-input current will be very small, though this input is a low-impedance node because of the buffer. In the limit \( z \to \infty \) we obtain \( I_\text{n} \to 0 \), indicating that a CF amp will provide whatever output voltage and current are needed to ideally drive \( I_\text{n} \) to zero. Thus, the conventional op amp conditions \( V_\text{n} = V_\text{p} \) and \( I_\text{n} = I_\text{p} = 0 \) hold for CF amps as well.

\[ z(jf) = \frac{z_0}{1 + j(f/f_a)} \]  

(14)

where \( z_0 \) is the dc value of the transimpedance gain, and \( f_a \) is the frequency at which rolloff begins. For instance, from the data sheets of the CLC401 CF amp (Comlinear Co.) we find \( z_0 = 710 \text{ k}\Omega \), and \( f_a = 350 \text{ kHz} \).

Substituting Eq. (14) into Eq. (13) and then into Eq. (12), and exploiting the fact that \( R_2/z_0 < 1 \), we obtain

\[ A(jf) = \frac{1 + R_2/R_1}{1 + j(f/f_a)} \]  

(15)

where

\[ f_a = \frac{z_0 f_a}{R_2} \]  

(16)

represents the closed-loop bandwidth, for \( R_2 \) in the k\Omega range, \( f_a \) is typically in the 100 MHz. Retracing previous reasoning, we see that the noise-gain curve is now \( R_2 \), and that \( f_a \) can be found graphically as the frequency at which this curve meets the \( |z| \) curve, see Fig. 6b.

Comparing with Eqs. (6) and (7), we note that the closed-loop gain expressions are formally identical. However, the bandwidth now depends only on \( R_2 \) rather than on the closed-loop gain \( 1 + R_2/R_1 \). Consequently, we can use \( R_2 \) to select the bandwidth, and \( R_1 \) to select the gain. The ability to control gain independently of bandwidth constitutes a major advantage of CF amps over conventional op amps, especially in automatic gain control applications. This important difference is highlighted in Fig. 7.

Absence of Slew-Rate Limiting

The other major advantage of CF amps is the inherent absence of slew-rate limiting. This stems from the fact that the current available to charge the internal capacitance at the onset of a step is proportional to the step regardless of its size. Indeed, applying a step \( \Delta V_\text{i} \) induces, by Eq. (11), an initial current imbalance \( I_\text{n} = \Delta V_\text{i}/(R_1 || R_2) \), which the Wilson mirrors then convey to the capacitor. The initial rate of charge is, therefore, \( I_\text{o}/C = I_\text{n}/C = \Delta V_\text{i}/[(R_1 || R_2)C] = \Delta V_\text{o}/[(R_1 || R_2)C] = \Delta V_\text{o}/(R_2C) \), indicating an exponential output transition with time-constant \( \tau = R_2C \). Like the frequency response, the transient response is governed by \( R_2 \) alone, regardless of the closed-loop gain. With \( R_2 \) in the k\Omega range and \( C \) in the pF range, \( \tau \) comes out in the ns range.

The rise time is defined as the amount of time \( \tau \) it takes for the output to swing from 10% to 90% of the step size. For an exponential transition, \( \tau = \tau \times \ln (0.9/0.1) = 2.2\tau \).

Fig. 6: Test circuit to find the loop gain, and graphical method to determine the closed-loop bandwidth \( f_a \).

No Gain-Bandwidth Tradeoff

The transimpedance gain of a practical CF amp rolls off with frequency according to

\[ z(jf) = \frac{z_0}{1 + j(f/f_a)} \]  

(14)
For example, the CLC401 has \( t_r = 2.5 \text{ ns} \) for a 2V output step, indicating an effective \( r \) of 1.14 ns. The time it takes for the output to settle within 0.1% of the final value is \( t_s = 7t \) in 1000 = 7r. For the CLC401, this yields \( t_s = 8 \text{ ns} \), in reasonable agreement with the data sheet value of 10 ns.

The absence of slew-rate limiting not only allows for faster settling times, but also eliminates slew-rate related nonlinearities such as intermodulation distortion. This makes CF amps attractive in high-quality audio amplifier applications.

Second-Order Effects

The above analysis indicates that once \( R_2 \) has been set, the dynamics of the amplifier are unaffected by the closed-loop gain setting. In practice it is found that bandwidth and rise time do vary with gain somewhat, though not as drastically as with conventional op amps. The main cause is the non-zero output impedance of the input buffer, whose effect is to alter the loop gain and, hence, the closed-loop dynamics.

Referring to Fig. 8a and denoting this impedance as \( R_o \), we note that the circuit first converts \( V_x \) to a current \( I_n = V_x/(R_2 + R_1||R_o) \), then it divides \( I_n \) to produce \( I_n = I_n R_1/(R_1 + R_0) \), and finally it converts \( I_n \) to the voltage \( V_o = z_l I_n \). Eliminating \( I_n \) and \( I_o \) and letting \( T = V_o/V_x \) yields \( T = z/Z_z \), where

\[
Z_z = R_2 \left( 1 + \frac{R_0}{R_1||R_2} \right) \tag{17}
\]

Thus, the effect of \( R_0 \) is to increase the noise gain from \( R_2 \) to \( R_2(1 + R_0/(R_1||R_2)) \), see Fig. 8b, curve 1. Consequently, both bandwidth and rise time will be reduced by a proportional amount.

Replacing \( Z_2 \) with \( Z \) in Eq. (16) yields, after simple manipulation,

\[
f_o = \frac{f_1}{1 + \frac{R_0}{R_2} \left( 1 + \frac{R_2}{R_1} \right)} \tag{18}
\]

where \( f_1 = z_0 f_o R_2 \) represents the extrapolated value of \( f_o \) in the limit \( R_0 \to 0 \). This equation indicates that bandwidth reduction due to \( R_0 \) will be more pronounced at high closed-loop gains. As an example, suppose a CF amp has \( R_0 = 500 \Omega, R_2 = 1.5 \text{ k}\Omega, \) and \( f_1 = 100 \text{ MHz} \), so that \( f_o = 10^6/(1 + (50/1500)A_0) = 10^6/(1 + A_0/30) \), where \( A_0 = 1 + R_2/R_1 \). Then, the bandwidths corresponding to \( A_0 = 1, 10, \) and 100 are, respectively, \( f_1 = 96.8 \text{ MHz} \), \( f_10 = 75.0 \text{ MHz} \), and \( f_100 = 23.1 \text{ MHz} \). Note that these values still compare favorably with a conventional op amp, whose bandwidth would be reduced, respectively, by 1, 10, and 100.

If so desired, the external resistance values can be predistorted to compensate for the bandwidth reduction at high gains. Turning Eq. (18) around yields the required value of \( R_2 \) for a given bandwidth \( f_o \) and gain \( A_0 \).

\[
R_2 = \frac{z_0 f_o}{f_1 A_0 - R_0 A_0} \tag{19}
\]

while the required value of \( R_1 \) for the given gain \( A_0 \) is

\[
R_1 = \frac{R_2}{A_0 - 1} \tag{20}
\]

As an example, suppose we want the above amplifier to retain its 100 MHz bandwidth at a closed-loop gain of 10. Since with \( R_2 = 1.5 \text{ k}\Omega \) this device has \( z_0 f_o R_2 = 100 \text{ MHz} \), it follows that \( z_0 f_o = 10^6 \times 1500 = 1.5 \times 10^8 \Omega \times \text{Hz} \). Then, the above equations yield \( R_2 = 1.5 \times 10^8/10^6 - 50 \times 10 = 1 \text{ k}\Omega \), and \( R_1 = 1000/(10 - 1) = 111 \Omega \).

Besides the dominant pole at \( f_o \), the open-loop response of a practical amplifier presents additional poles above the crossover frequency. As shown in Fig. 8b, the effect of these poles is to cause a steeper gain rolloff at this frequency, further reducing the closed-loop bandwidth. Moreover, the additional phase-shift due to these poles decreases the phase margin somewhat, thus causing a small amount of peaking in the frequency response, and ringing in the transient response.

Finally, it must be said that the rise time of a practical CF amp does increase with the step size somewhat, due primarily to transistor current gain degradation at high current levels. For instance, the rise time of the CLC401 changes from 2.5 ns to 5 ns as the step size is changed from 2V to 5V. In spite of second-order limitations, CF amps still provide superior dynamics.

CF Applications Considerations

Although the above treatment has focused on the non-inverting configuration, the CF amp will work as well in most other resistive feedback configurations, such as the inverting amplifier, the summing and differencing amplifier, I-V and V-I converters, and KRC active filters. In fact, the derivation of the transfer characteristic of any of these circuits proceeds along the same lines as conventional op amps. Special consideration, however, require the cases in which the feedback network includes reactive elements, either intentional or parasitic.

Consider first the effect of a feedback capacitance \( C_2 \) in parallel with \( R_2 \) in the basic circuit of Fig. 8a. Letting \( Z = R_2/(1/s C_2) \), the noise gain becomes \( Z_2 = Z[1 + R_0/(R_1||Z)] \). After expanding, it is readily seen that the noise-gain curve has a pole at \( f_p = 1/(2 \pi R_2 C_2) \) and a zero at \( f_z = 1/(2 \pi R_0/(R_1||R_2) C_2) \), as shown in Fig. 8b, curve 2. Consequently, the crossover frequency will be pushed into the region of substantial
phase shift due to the higher-order poles of $z$. If the overall shift reaches $-180^\circ$ at this frequency, then $T = 1 / (-180^\circ) = -1$ there, indicating that $A$ will become infinite by Eq. (12), and the circuit will oscillate. Even if the phase shift fails to reach $-180^\circ$, the closed-loop response may still exhibit intolerable peaking and ringing. Hence, capacitive feedback must be avoided with CF amps. To minimize the effect of stray feedback capacitances, manufacturers often provide $R_2$ internally.

**CF Integrators**

To synthesize the integrator function in CF form, which provides the basis for dual-integrator-loop filters and oscillators as well as other popular circuits, we must use configurations that avoid a direct capacitance between the output and the inverting input. One possibility is offered by the Deboo integrator,\(^4\) which belongs to the class of KRC filters and is therefore amenable to CF realization. Its drawback is the need for tightly matched resistances, if lossless integration is desired. The alternative of Fig. 9 not only meets the given constraint, but also provides active compensation, a highly desirable feature to cope with Q-enhancement problems in dual-integrator-loop filters.\(^4\) Using standard op amp analysis techniques, it is readily seen that the unity-gain frequency of this integrator is $f_0 = (R_2 / R_1) / (2\pi RC)$.

![Fig. 9: Actively-compensated CF integrator.](image)

**Stray Input-Capacitance Compensation**

Next, consider the effect of an input capacitance $C_1$ in parallel with $R_1$ in the basic circuit of Fig. 8a. Letting $Z = R_1 || (1/SC_1)$, the noise gain is now $Z_2 = R_2 [1 + R_0 / (Z || R_2)]$. After expanding, it is readily seen that the noise-gain curve has a zero at $f_z = 1 / \left[2\pi \left(\frac{R_0 || R_2 || R_2}{R_1}\right)C_1\right]$, as shown in Fig. 8b, curve 3. If $C_1$ is sufficiently large, the phase of $T$ at the crossover frequency will again approach $-180^\circ$, bringing the circuit on the verge of instability. This is of particular concern in current-mode DAC output buffering, where $C_1$ is the output capacitance of the DAC, typically in the range of a few tens to a few hundreds of picofarads, depending on the DAC type.

![Fig. 9: Actively-compensated CF integrator.](image)

Like a conventional op amp, the CF amp can be stabilized by using a feedback capacitance $C_2$ to introduce sufficient phase-lead to compensate for the phase-lag due to the input capacitance $C_1$. For a phase margin of $45^\circ$, choose the value of $C_2$ so that the noise-gain pole $f_p = 1 / (2\pi R_2 C_2)$ coincides with the crossover frequency $f_0$, as shown in Fig. 10a. Using asymptotic Bode-plot reasoning,\(^4\) it is easily seen that $f_A = \left[\frac{C_1 f_0}{(R_0 + R_2)^2}\right]^{1/2}$, where $f_z = 1 / \left[2\pi \left(\frac{R_0 || R_2 || R_2}{R_1}\right)C_1\right]$. Imposing $f_p = f_A$ yields

$$C_2 = \left(\frac{R_0}{2\pi R_2 f_0} C_1\right)^{1/2}$$

(21)

![Fig. 10: DAC output capacitance compensation.](image)

To cope with impractically low values of $C_2$, it is convenient to drive $C_2$ with a voltage divider as in Fig. 10b, since this will scale the value of $C_2$ to the more practical value

$$C_c = \left(1 + \frac{R_B}{R_A}\right) C_2$$

(22)

It can be shown that for this technique to be effective we must choose $R_B \ll R_2$. As an example, suppose a DAC having $C_1 = 100$ pF feeds the CF amp considered earlier. Then, Eq. (21) yields $C_2 = \left[50 \times 100 \times 10^{-15} / (2\pi \times 1.5 \times 10^3 \times 1.5 \times 10^3)\right]^{1/2} = 1.88$ pF. To scale it to a more practical value, use $^5 R_A = 50\Omega$ and $R_B = 500\Omega$. Then, $C_c = (1 + 500/50) 1.88 = 21$ pF. This estimate may require some fine tuning to optimize the transient response.

Additional useful application hints can be found in Ref. [5].

Application Note 103-1

“Flash” Analog to Digital Converters: Optimizing Performance

Wayne Lonowski
INTRODUCTION

Flash analog-to-digital converters have gained popularity due to their extremely high conversion rates and their potential for use in digitizing wideband analog signals. Flash converters have a substantial speed advantage over other conversion techniques such as successive approximation and dual-slope integration. However, many of the problems encountered with slower speed A to D techniques are accentuated in flash applications, and a myriad of new considerations must be addressed.

This application note presents pertinent background information on A to D conversion as well as the basics of flash A to D techniques. Finally, this note addresses practical considerations vital to the successful implementation of a flash A to D converter.

BACKGROUND

There are a few fundamental considerations that are critical in any A to D conversion system. The first is sampling rate. Sampling rate establishes a ceiling on the frequency of the signals that the digitizer can process accurately. The Nyquist sampling criterion states that defining a sinusoidal input signal in terms of its frequency and amplitude requires at least two samples per cycle. As an example, in a system with a 10MHz sampling rate, the highest frequency component that the digitizer can accurately define is 5MHz.

A related topic is aliasing. The relationship of a continuous time Fourier transform of an analog signal and the fourier transform of a sequence derived by sampling that signal is such that the upper frequencies of the continuous time transform may be reflected into the lower frequencies of the sampled transform. This phenomenon, where a high frequency component takes on the identity of a lower frequency, is called aliasing (See Figure 1). To avoid this, the analog signal must be sampled at a rate at least twice the frequency of any signal (or its harmonics) which has an amplitude of at least one-half LSB.

![Sampled Signal](image)

Figure 1: Inadequate sampling of the input waveform produces aliasing errors. If the sampling rate is slightly less than twice per cycle, an apparent low frequency sinusoid is created as part of the recovered signal.

This can impose some formidable restrictions. For example, for 8 bits of resolution, one-half LSB represents .2% of a full scale input. If an ideal square wave is being sampled, the first 635 harmonics have amplitudes of .2% or greater. Thus, if the fundamental frequency is 1MHz, the needed sampling rate is 2(635)(1MHz) = 1.27 GHz! Fortunately, most applications have significantly lower harmonic levels so that sampling rates can be several times lower.

As a rule of thumb, signal components within [(n+1) (6dB)] of full scale are significant in an n-bit system. To digitize a 20MHz sine wave with a third harmonic at -54dB to 1/2 LSB accuracy and 8-bit resolution, 2(3(20MHz)) = 120MHz sampling rate is necessary.

FLASH A TO D CONVERTERS

A flash, or parallel, converter is composed of an array of parallel comparators, each representing one out of 2^n quantization levels. The analog signal is applied simultaneously to all of the comparator inputs as shown in Figure 2. The other input to each comparator is connected to a tap in a resistor divider network. The resistor network establishes reference voltages for each comparator.

The relationship between the number of comparator cells and the number of bits to be digitized is as follows:

- 4-bits = 16 comparator cells
- 6-bits = 64 comparator cells
- 8-bits = 256 comparator cells
- 10-bits = 1024 comparator cells

This technique provides a method for A to D conversion of signals in the tens of megahertz.

A technique used for high resolution A to D conversion is the two-stage approach, as illustrated in Figure 3. The most significant bits are developed by the first converter. These bits are fed to a D to A converter which develops a signal current equivalent to the value of these bits. This signal is then applied to an amplifier's summing node where it is nulled against the input signal (after correcting for propagation delay). Any remainder is amplified, then A to D converted by the second converter. This technique allows the use of 6 or 8-bit converters to produce 10 to 12-bit (or more) conversions.

![Figure 2](image)

Figure 2: This is a simplified schematic of a flash A to D converter. The analog signal is applied to all of the comparator cells simultaneously allowing the entire conversion to be made at once.
Figure 3: A two-stage flash A to D converter views the input voltage in two steps. The most significant digits are developed and a precision D to A converter is used to null that portion of the input voltage. The remainder is amplified and applied to a second A to D converter. The digitized results from both converters are combined in a binary adder to produce the final reading. The key is in the precision amplifier selected.

PRACTICAL CONSIDERATIONS

System Bandwidth

Some of the greatest challenges in high-speed A to D conversion involve the drive circuitry. Ideally, the analog signal path would have an overall bandwidth less than or equal to the Nyquist frequency (i.e. one-half of the sampling rate) to avoid aliasing problems. Due to a prior lack of commercially-available DC coupled amplifiers with sufficient high frequency performance, in many applications the amplifier has acted, by default, as the low pass (anti-aliasing) filter. To limit bandwidth, however, by selecting an input amplifier with its rolloff point at or near the Nyquist frequency is a mistake. Phase becomes non-linear in most amplifiers at greater than one-third to one-half of the 3dB bandwidth. Group delay is, therefore, not constant and harmonics are delayed unequally. The net result is distortion, and degradation of the system's ability to accurately convert signals.

Thus, it is important to maintain amplifier bandwidth of at least three times the Nyquist rate to minimize gain and phase aberrations. Then, the anti-aliasing filter can be designed independently of the less precisely controlled transfer function poles of the amplifier and sample-hold. To attempt to do otherwise means that a custom filter must be designed for each samplehold and amplifier set.

Driving Capacitance

In a flash type converter, the input amplifier must drive a non-linear capacitance in parallel with a non-linear resistance. This non-linearity is due to the dramatic changes possible in the input impedance characteristics of the comparators, depending on whether they are in their on or off state. To minimize the consequences of changing capacitance, flash converter manufacturers recommend a fast settling, wide bandwidth, high slew rate, low output impedance driver. Comlinear amplifiers meet all of these requirements.

Specifically, capacitance connected from the output of a closed-loop amplifier to ground can cause loop instability and even oscillation. The CLC409, however, remains stable even under these demanding circumstances. Experiments have shown that the circuit in Figure 4 will provide maximum bandwidth, flatness, and settling time when driving capacitances of up to 650pF.

Figure 4: Experimental results indicate that this circuit offers the best bandwidth, flatness, and settling time for driving capacitive loads of up to 300pF in flash A to D converter applications.

R₁ serves to isolate the input capacitance, Cᵢ, from the amplifier. This cuts down amplitude peaking. Although the optimum value of R₁ depends on converter parameters, the curve of Figure 5 gives a good first approximation. If Cᵢ = 50pF, and R₁ value of 32Ω works very well.

As Cᵢ gets larger, R₁ gets smaller to keep the RC pole at the highest possible frequency while maintaining peaking levels at less than 0.5dB. For example, when the amplifier drives 200pF, an R₁ value of 16Ω results in a -3dB bandwidth of 50MHz. Peaking is about 0.25dB, and settling time to 0.2% is about 15ns. Note that as R₁ decreases, overall gain increases.
Figure 5: When the amplifier drives capacitive loads, resistor $R_s$ in Fig. 8 isolates it from the input capacitance, $C_{in}$. This curve will give a good first approximation for the value of $R_s$. The optimum value depends on several factors.

**Settling Time**

For A to D conversion of pulse waveforms, settling time of amplifiers and sample-holds is an important measure of waveform reproduction fidelity. These components must be able to settle to within one-half LSB of the correct value within the sample period allotted. Thus, for use with an 8-bit 100MHz flash A to D converter, settling to .2% within 10ns is necessary. This is a stringent requirement, but unless it is met the full capabilities of the flash A to D converter cannot be realized.

**Slew Rate**

Another consideration is the slew rate of the drive circuitry. The maximum slew rate for a sine wave is:

$$\frac{dv}{dt} = 2\pi f A \text{ Volts/second}$$

Therefore, to digitize a 5V peak sine wave at 20MHz, a slew rate of 630V/µs is needed. It is always a good idea to use an amplifier with much higher slew rate than that actually needed, because once an amplifier comes close to slew rate limiting, it becomes very non-linear and fails to settle properly.

**Aperture Uncertainty**

Ideally, digital conversion should occur at the center of the sampling window. However, noise can jitter the window aperture and create uncertainty as to its location in time. This causes uncertainty in the sample amplitude and is strongly dependent on signal slope, and hence on the frequency of the signal. So, while an A to D may have an impressive sample rate, unless its own aperture uncertainty (as well as that of the sample-hold) is low, the maximum frequency at which full n-bit accuracy can be obtained will decrease. For total aperture uncertainty of $t$, the maximum signal frequency that can be accurately digitized is $(3.142^{n+1})^{-1}$. Thus, for $t=20$ps and $n=8$, the maximum signal frequency is 31MHz.

This problem becomes severe when two high speed flash converters are combined in a two-stage converter which is designed to increase resolution. Not only does $n$ become larger, maybe 10 to 12 in most cases, but $t$ increases by at least a factor of two due to increased complexity. For example: two 6-bit flash A to D's which are capable of 100MHz sampling are to be used in such a system to give 10 bits of resolution, with $t=40$ps. This limits the signal frequency to 3.9MHz if 10-bit accuracy is also required. If a 20MHz signal were to be digitized with this system, the result would have 10 bits of resolution but only 7.6 bits of accuracy. Note, however, that this is adequate for most applications, because resolution is usually of greater importance. This example illustrates why amplifiers and sample-holds with only 8 bits of accuracy work well in these systems.

**Comparator Uncertainty**

In parallel converters, comparator uncertainty may also become a limiting factor. An 8-bit converter capable of digitizing 2V must divide the voltage into 256 levels or 7.8mV per level. Given the typical comparator uncertainty of ±2mV, this represents an uncertainty of 25%. The problem of comparator uncertainty becomes even more severe as resolution increases.

**CONCLUSION**

The need for higher speed analog-to-digital conversion is being answered by flash conversion techniques. However, these techniques have some critical considerations that must be understood and addressed if a successful converter is to be implemented. Many of these considerations relate back to the drive amplifier, making it a critical component in flash A to D applications. Due to their bandwidth, speed, and drive capabilities, Comlinear amplifiers are ideal for most flash converter applications.
Designing with High-Speed Analog-to-Digital Converters

Mark Sauerwald
Designing with High-Speed Analog-to-Digital Converters

By: Mark Sauerwald

Introduction
State-of-the-art A/D converters push the very limits of performance by definition. This level of performance generally comes at a price: power dissipation, physical size, cost, etc. Balancing this situation is the fact that most systems are limited by the performance of lesser converters, and employing the very best converter is generally necessary to get the best overall system performance. By squeezing every last bit of performance out of a converter, the system specifications can be enhanced and great savings may be possible.

This guide to designing with high-performance A/D converters, should help to ensure that every design will “be all that it can be”. This application note is split into several sections, many of these sections are built upon the others. Accordingly, the application note should be read through rather than just focusing on specific sections that explain a particular issue.

Power Supplies, Grounding and Bypassing
Without proper grounds, an A/D converter is incapable of providing quality data. What therefore constitutes a ‘good ground’? Unfortunately, this is a question whose answer is difficult to nail down, since it varies from system to system. Ideally, a single ground plane with 0Ω impedance, both AC and DC, back to a power supply would be used in every system. In reality there is a finite impedance, and since the ground currents vary, the ground potential varies as well. To keep these effects in check, both the impedance to ground, and ground current variations in the path from the A/D converter back to the power supply, must be kept to a minimum.

To minimize the ground impedance seen by the power supply return currents, generous amounts of copper between the A/D and the power supply are the answer. In the best of situations, a layer of the printed circuit board would be dedicated to power supply grounding. Which layer should be used? The outer layers will often provide a higher measure of shielding, and may be preferable. In any case, 2oz/ft² or greater copper weight should be considered to lower the low-frequency ground plane impedance and keep ground plane potentials to a minimum.

The designer has less control over the variation in ground currents. In general analog circuits have a near constant current drain with time, while digital circuits experience much more variation, as transistors move in and out of saturation. Selection of the logic family will have a significant impact. Best for the A/D is a logic family which employs non-saturating transistor designs such as ECL. Worst is CMOS, which only draws supply current during clock edges.

Given that digital switching transients are composed largely of high-frequency components, total ground plane copper weight will have little effect on the ground impedance seen by the transients. This is because high-frequency currents tend to travel only on the surface of conductors (skin-effect) and total surface area is more critical than total ground plane volume.

Be aware of your logic power requirements. Current surges can be decreased through extensive bypassing. Even though the digital logic may not need it, providing a bypass capacitor for every power pin will minimize interference from the digital circuits on the converter’s power supply. Ceramic 0.1µF capacitors are recommended for each power pin in the system. Also, a larger electrolytic or tantalum capacitor (+5µF to +10µF) should be used on each of the power supply feeds on each printed circuit board in the system.

Since the impedance of an electrolytic or tantalum increases with increasing frequency above about 10kHz, large capacitors on the power supplies do not eliminate the need for the per-pin ceramic capacitors which are primarily there to reduce high frequency transients. Chip capacitors have several advantages over the through-hole variety. They are smaller, and can often be placed closer to the pin that they are trying to bypass. Since they have no leads, series inductance is lower.

Many of the undesirable effects seen on A/D converter boards containing significant amounts of digital circuitry can be avoided by employing “single point” grounding. At a minimum, the analog and the digital supply and return currents should take separate paths back to the power supply. See figures 1a and 1b for the right and wrong way to do this. In figure 1a, the time varying power and ground currents are multiplied by the trace impedance between the A/D and the power source, increasing the ground potential fluctuations seen by the converter. In figure 1b, the impedance of the common portion of the current paths is much smaller, minimizing the effect on the A/D.
Many A/D converters are capable of corrupting their own power supplies, if it is not adequately bypassed itself. A 5μF to 10μF tantalum or electrolytic capacitor should be placed within a couple of inches of the A/D converter, with 0.1μF ceramic chip capacitors placed as close as possible to each of the converter's power supply pins. Since chip capacitors are smaller than their leaded counterparts, they are easier to locate close to the supply pins, providing lower lead inductance.

Printed Circuit Board Layout

As mentioned in the section on power supplies and grounding, the board layout can have a profound effect on the A/D converter's performance. Besides power supplies and grounding, there are other ways in which the converter's performance can be affected by board layout. A key to good performance lies in getting "uncorrupted" clock and analog input signals to the A/D converter. If the clock line has noise on it, or is capacitively coupling to another signal, a slight non-periodicity can be introduced into the sampling process. As discussed in the section on clocks, this is not good, and a seemingly minor contamination of the clock can cause very undesirable effects.

Once the analog input signal has been sampled, clock jitter is not a major concern, special care is necessary only between the clock source to the A/D converter. This path should be as short as practical, and the clock line should be kept as far away from other signal traces as is reasonable, especially high-frequency traces. If the clock must cross over another trace, it should do so at a 90° angle to minimize coupling.

If the A/D requires a differential clock signal, the trace lengths of the two lines should be equal. If the two clock traces are not equal length, the edges of the convert command may arrive at the A/D at different times. This would increase, rather than cancel, the capacitive coupling of the clock to the analog input.

The analog input to the A/D converter requires the same attention. Running the trace to the analog input near to or parallel to digital traces will degrade the quality of the input signal during sampling. Try to avoid getting the analog input trace near any digital signals, if it must cross a digital path, try to make the crossing at 90°.

Use of a Balun for Impedance Control

When the converter is in a harsh environment, or at the end of a long transmission line, there may be an appreciable amount of common mode noise between the ground and input signal. Much of this common mode noise can be eliminated through the use of a balun (figure 2). A balun is a 1:1 transformer which forces equal currents in the signal and ground paths, forming a common mode choke. When a Balun is used, it will modify the frequency response of the system, adding insertion loss at both high and low frequencies. A balun such as the T2.5-6 from Mini-Circuits will allow for less than 0.2dB of loss for frequencies from 60kHz up to over 10MHz. Other transformers will have different frequency characteristics and should be selected after considering the application requirements.
Analog Input Driving Circuits
Most hybrid A/D converters, and all of Comlinear's 12-bit converters, have their own internal buffers. In many cases no amplifier is required to drive the A/D converter analog input. If, however, there is need for an analog input driver circuit for gain or other signal conditioning, the CLC207 and CLC409 are very low distortion amplifiers (figure 3). Both have been optimized for high-gain applications, and can be configured for better than -80dBc harmonic suppression.

Digital Interface
If there is significant digital processing to be applied to the A/D output, it is suggested that a separate circuit board be used for the A/D so that the large number of digital signals do not degrade A/D's performance. If this is not practicable, then the following guidelines should be followed:

1) Use a non-saturating, low swing, logic family ... such as ECL. If ECL logic can be used, select the slowest possible TTL logic family; the slower edge rates will couple less effectively to the analog circuitry.

2) Make the system completely synchronous, using the same clock for the A/D converter and digital processing. A/D converters are most susceptible to interference in the middle of the conversion cycle, clock edges at this time are very undesirable.

3) Physically and electrically isolate the digital logic from the A/D converter and the analog circuitry as much as possible. Bypass power supplies that are in common both with capacitors to ground and series inductors as suggested in the section on power supplies.

4) Employ latches or buffers on the A/D converter digital outputs. This will prevent digital noise from entering and corrupting the conversion process through the outputs themselves. The performance of nearly all high performance A/D converters is degraded when driving high fanout loads or significant trace lengths.

Convert Clock Generation
All high-speed high-resolution A/D converters are sensitive to the convert clock quality. With a full scale 7MHz analog input signal, the slew rate at the 0V crossing is 14LSB/ns (for a 2Vp-p analog input signal). An error (jitter) of as little as 35ps in the clock edge will yield a 0.5LSB error at the A/D converter output. This is as great or greater than any other error source likely to be present. This type of clock error or clock jitter is most easily seen in the form of poor SNR (signal-to-noise ratio). If the SNR is below expectations, clock jitter should be investigated.

\[
SNR_{MAX} = 20\log \left( \frac{1}{2\pi f_c \text{jitter}_{\text{RMS}}} \right) \\
\text{where} \ldots
\]

\[
\text{jitter}_{\text{RMS}} = \sqrt{(\text{clock jitter}_{\text{RMS}})^2 + (\text{analog jitter}_{\text{RMS}})^2}
\]

It should also be noted that jitter in the analog input source will have the same detrimental affect on SNR. Analog input signal jitter is usually only a problem in evaluation setups, and does not generally present a problem in full systems.

Low-jitter crystal controlled oscillators make the best convert clock sources. If the convert clock is generated from another type of source, by gating, dividing or other method, it should be registered by the original clock as the last step. This should keep jitter terms from compounding.

For variable frequency convert clocks, low-phase-noise frequency synthesizers like the Fluke 6080A or the HP8662 are good choices. Sinusoidal sources of this type will require a sine-to-ECL conversion circuit (figure 4), such as the one above. This circuit operates consistently with low level inputs (0dBm), but is sensitive to noise (jitter) from the synthesizer. By maintaining a larger input level (>6dBm), the effects of jitter can be greatly minimized.

Thermal Considerations
Many high performance A/D converters dissipate an appreciable amount of power, up to 6W in some cases. The following strategies can be applied to prevent overheating:

a) ... a thick copper ground plane ... an appreciable amount of heat is conducted out of the A/D through its leads.

b) ... a copper stand-off between the ground plane and the bottom of the package (thermal paste may be useful).
c) ... a SIL PAD* between the ground plane and the bottom of the package. To maximize heat conduction leave a patch of exposed (no solder mask) ground plane under the A/D converter.

d) ... moving air over the A/D converter.

Evaluating a high performance A/D converter
Since the A/D converter is an expensive component, and one which can have a great effect upon the system performance. The best approach is to evaluate performance in the target system. This is not always feasible, and often clouds the line between converter and system quality. If the design is an upgrade of an existing design, try to modify the existing system, using an evaluation board to replace the old data converter.

If it is not practical to employ the final system as an evaluation platform, the converter should be operated under conditions as close as possible to those of the intended use. Match the clock rate; use input signals that are comparable in size and bandwidth to those in the final system.

If the system uses an 11MSPS clock, A/D performance with an 11MSPS clock may be better or worse than performance at the rated speed. Many manufacturers define the same specification differently, or test the parameter differently, it is therefore dangerous to try and make a comparison of two devices based on data sheet specifications alone. If in the application, the converter is sampling a signal with 5MHz bandwidth, a test of D.C. linearity will not be particularly illuminating. SNR or SFSR (or any other test pertinent to the final application) may be more relevant to the application. Comlinear applications engineers stand ready to assist you in evaluating Comlinear or competitive A/D converters.

A/D Converter Specifications
As the speeds and resolutions of A/D converters have increased, A/D converters have found themselves in applications that once were entirely analog. In an attempt to make the transition from analog to digital easier for the design engineer, Comlinear specifies many parameters in ways that are similar to those of analog components intended for the same systems. Unfortunately since there is not a direct equivalence between the A/D and the analog function that it is replacing, the specifications do not have the same meaning as similarly named specifications for analog components. What follows is a listing of several of the parameters that are used in many A/D converter specification sheets, along with the definitions that Comlinear uses.

Small Signal Bandwidth
In testing small signal bandwidth, the input is a sinusoid with a peak-to-peak amplitude of +FS (one half of the Full-Scale range for a bipolar input converter). The input frequency of a sinusoid is raised until the amplitude repre-
SNR - [Σ of the Noise (less Harmonics) : Fundamental]
Signal-to-Noise Ratio is a measure of the broad band noise that is introduced into the signal by the A/D converter and the sampling process. The magnitude of the input sinusoid is compared to the sum of all other frequencies, except for those representing harmonics of the fundamental frequency. The ratio of the signal to the sum of the individual noise components is the SNR.

THD - [Σ Harmonics (10 to 50 Harmonics) : Fundamental]
Total-Harmonic-Distortion is measured in a similar fashion to SNR, except that in the analysis, the fundamental is compared to the sum of the harmonics. Since some of the harmonics lie outside the dc to f/2 range, they will be aliased back into the baseband.

IBH - [Largest Harmonic component : Fundamental]
IBH is the ratio of the fundamental to the largest harmonic.

SINAD - [Σ of the noise and Harmonics : Fundamental]
SINAD is similar to SNR except that the harmonics are not ignored.

SFSR - [Largest Harmonic or Noise component : Fundamental]
SFSR is the ratio of the fundamental to the highest spur (noise or harmonic) in the frequency domain. This is very similar to IBH since the highest spur is usually harmonically related to the input.

Two Tone Intermodulation Distortion -
[Largest Harmonic or IMD component : Fundamental]
The input to the A/D Converter consists of the sum of two sinusoids with a small difference in their frequencies. As an example, a converter with a 15MSPS clock might be tested with inputs at 5.1MHz and 5.2MHz. Non linearities in the converter will cause the input frequencies and their harmonics to mix, generating products at the frequencies Nf_1 + Mf_2 where N and M are integers and f_1 and f_2 are the input frequencies. Many of these products will lie outside the dc to f/2 band, but their images will alias back into the baseband. The two tone I.M.D. is the ratio of the input signal to the largest of these unwanted products.

NPR - Depth of notch in an "all hostile" noise environment
Noise Power Ratio is determined by providing the A/D converter with a "band limited" white noise input signal, with a narrow range of the spectrum removed from the input (this is the "all frequencies hostile" except the notch). The ratio of the power level in the spectrum to that in the notch, is the NPR (see figure 6). NPR is a useful specification for systems in which the input comprises several independent signals separated in the frequency domain. The NPR will predict how much adjacent channels will interfere with each other.

Evaluation Boards
An evaluation board available for all of Comlinear's A/D converters. The evaluation board can be used to quickly evaluate the performance of these converters, saving time and effort. Use of the evaluation board, as a proven circuit layout, is highly recommended.

INTRODUCTION

No two high-speed applications are the same—or at least it seems that way. Nonetheless, while every system has its particular requirements, many of the design techniques are common among different designs. This application note illustrates design techniques utilizing current-feedback op amps and the practical circuits where they are used. The circuits should work well with any Comlinear op amp if appropriate adjustments are made for different feedback resistance values.

Inverting Gain

As with voltage-feedback op amps, the ratio of the feedback resistor to the gain-setting resistor determines the voltage gain in current-feedback op amp circuits. With current feedback, however, dynamic performance is largely independent of the voltage gain. (See application note AN300-1 for a technical discussion of current-feedback.) Also, the optimum feedback resistor value for a current-feedback op amp is indicated in the data sheet.

Differential Amplifier

Be sure to obey common-mode input voltage limits shown in the op amp data sheet. If large, saturating input signals are expected, use an overdrive-protected op amp and appropriate protection circuitry.

\[ V_{out} = V_{o} - V_{i} \]

Differential Line Receiver

This circuit provides good common mode rejection and 50Ω termination for signals which need to be transmitted through coaxial lines.

\[ V_{out} = V_{2} - V_{1} \]

Differential input resistance is 50Ω.

Coaxial Cable Driver

Proper transmission line driving techniques are important when high-speed signals have to travel more than a few inches. The back-matching and terminating resistors, \( R_o \), are chosen to match the characteristic impedance of the coaxial line. If the load is well-matched to the transmission line impedance, the back-matching resistor may be omitted for greater voltage swing. (Remember that back matching creates a voltage divider which attenuates the output signal by 50%.)

\[ R_o = |Z_o| \]

Distribution Amplifier

\[ V_{out} = V_{o} \]

Driving Capacitive Loads

The damping resistor, \( R_s \), reduces pulse-response overshoot and frequency-response peaking caused by the load capacitance. The value of \( R_s \) may be found on some of the op amp data sheets or may be found experimentally.

Output Current Booster

This circuit provides up to 400mA of output current. Since the output buffer circuit introduces additional phase lag, the feedback resistor, \( R_f \), may have to be increased above the data sheet recommendation to decrease loop gain and thus improve stability. The gain-setting resistor, \( R_g \), is then chosen for the desired gain.
Simple Offset Adjustment

The Zener diode biasing resistor, $R$, should be chosen to provide a diode current of 7.5mA.

Composite Amplifier for Low Offset and Drift (#1)

This composite circuit provides both high speed and good DC performance and unlike most composite circuits, it provides good settling performance (17ns to 0.1%). In operation, the OP-27 op amp drives its output such that the summing node is driven to 0V (which is the normal case for an inverting gain circuit). Thus, the circuit output takes on the high-performance DC characteristics of the OP-27. At high frequencies, the high-speed op amp takes over to provide good AC performance.

Non-Inverting Composite Amplifier

As with the previous circuit, $R_b$ is chosen for minimum output voltage at the OP-27 when $V_{out}$ is a 70kHz square wave of 10Vpp centered at 0V.

FET-Input Circuit

A FET-input circuit is useful when a greater input impedance is desired or when bias currents or noise currents need to be reduced.
AC-coupled Amplifier (with Single-Supply Biasing)

The voltage divider circuit at the non-inverting input biases the op amp input and output at the supply midpoint. For those op amps having a bias pin, these pins should also connect to the supply midpoint bias circuit.

Reducing Bandwidth

Bandwidth and loop stability is controlled by $R_f$. Increasing $R_f$ reduces bandwidth according to the approximate relationship: $\frac{BW_2}{BW_1} \approx \frac{R_{11}}{R_{12}}$

Adjustable Bandwidth

By increasing the inverting input impedance (which is normally very low) of a current feedback op amp, the bandwidth of the op amp can be reduced. The bandwidth of the circuit below can be varied over a range of 60MHz to 160MHz.

Reducing Frequency-Response Peaking

(due to stray capacitance in parallel with $R_g$)

The low-pass filter at the non-inverting input cancels the frequency-response zero caused by $C_{stray}$. At low non-inverting gains, the CLC231 or CLC400 will provide a flatter frequency response without the need for the low-pass filter (because they can be used with lower feedback resistor values).

Adjustable Gain Using a FET

This circuit provides a 26dB adjustment range and a gain flatness of 1dB from DC to 50MHz. An SD210 FET provides low on-resistance with minimal capacitive loading.

Adjustable Gain Using a Photoresistor

This circuit provides a 12dB adjustment range and a gain flatness of 1dB from DC to 20MHz. The 741 circuit improves temperature stability and repeatability of the photoresistor circuit.

Integrator (#1)

With current-feedback op amps, it is important to keep large capacitance values out of the inverting feedback loop in order to maintain stability.
Integrator (#2)

This integrator provides higher dc gain than #1. For the values shown, the dc gain is 55dB. Higher values can be obtained by reducing \( R_g \), however, the ratio of \( R_g \) to \( R_1 \) should remain constant for adequate loop stability. Much of the output noise is directly proportional to \( R_g \), so that higher dc gain is obtained at the expense of higher noise. This circuit does not have the stability problem that is related to resistor matching as does integrator #1.

\[
V_{out} = \frac{R_g}{R_1} \frac{v_i}{sRC} = v_i \cdot 2\pi(12.7MHz)
\]

Integrator with Zero

In this circuit, feedback capacitance is acceptable because the op amp relies upon the value of the feedback resistor for stability.

\[
V_{out} = -\frac{R_2}{R_1} \frac{1}{s} + \frac{1}{R_f C}
\]

Active Filter Circuits

The following five circuits illustrate how current-feedback op amps provide high-performance active filter functions. The “KRC” realization is used (see references at the end of the ap note) since it doesn’t require reactive elements in the (negative) feedback path, which would compromise stability.

When the filter cutoff frequency is small relative to the amplifier bandwidth, the transfer functions shown will provide good accuracy. However, as with any active filter circuit, the group delay through the op amp becomes significant for cutoff frequencies greater than about 10% of the op amp bandwidth. For such designs, computer analysis tools and an iterative design approach is helpful.

Low-Pass Filter (10MHz, Q = 5)

\[
V_{out} = \frac{K_u}{s^2 + \frac{1}{R_1 C_1} + \frac{1}{R_2 C_2} + \frac{1-K_u}{R_3 C_3} + \frac{1}{R_1 R_2 C_2}}
\]

\[
K_u = 1 + \frac{R_k}{R_0} \quad \omega_0 = \frac{1}{R_1 R_2 C_2} \quad Q = \frac{1}{3 - K_u}
\]

High-Pass Filter (1MHz, Q = 2)

\[
V_{out} = \frac{K_u s^2}{s^2 + s \left( \frac{1}{R_1 C_1} + \frac{1}{R_2 C_2} + \frac{1-K_u}{R_3 C_3} \right) + \frac{1}{R_1 R_2 C_2}}
\]

\[
K_u = 1 + \frac{R_k}{R_0} \quad \omega_0 = \frac{1}{R_1 R_2 C_2} \quad Q = \frac{1}{3 - K_u}
\]
Band-Pass Filter (40MHz, Q = 4)
The component values shown are “predistorted” from the nominal design values to account for the 1.6ns op amp group delay, which is significant relative to the filter cutoff frequency.

\[
V_{\text{out}} = \frac{K_o}{s^2 + \left(\frac{1}{R_1C_1} + \frac{1}{R_2C_2} + \frac{1}{R_3C_3} + \frac{1-K_o}{R_4C_4} + \frac{1}{R_5}\right)}
\]

\[
K_o = 1 + \frac{R_f}{R_o}
\]

\[
\omega_o = \frac{\sqrt{2}}{\sqrt{sRC}}
\]

\[
Q = \frac{\sqrt{2}}{4(1-K_o)}
\]

Band-Stop Filter (4MHz, Q = 4)

\[
V_{\text{out}} = \frac{K_o}{s^2 + \frac{s}{s + \frac{1}{RC}(2 - K_o) + \frac{1}{RC^2}}}
\]

\[
K_o = 1 + \frac{R_f}{R_o}
\]

\[
\omega_{\text{zero}} = \omega_{\text{zero}} = \frac{1}{\sqrt{2}}
\]

\[
Q_{\text{zero}} = \frac{1}{2(2 - K_o)}
\]

Photodiode Amplifier
The circuit below provides a transimpedance gain of -2.5k\(\Omega\) to convert the photodiode current into a voltage.

D/A Converter Buffer Amplifier
Most high-speed, current-output D/A converters provide the best performance when driving little or no load impedance. The circuit below meets this requirement while also providing a transimpedance gain which converts the D/A output current into a voltage. The variable capacitor in the feedback loop should be adjusted for desired pulse response to compensate for the D/A output capacitance, which otherwise causes frequency-response peaking or instability. The 50\(\Omega\) and 500\(\Omega\) resistors reduce the effective value of the feedback capacitance so that a reasonable value capacitor may be used.

Tunnel Diode Detector Amplifier
See the D/A converter buffer circuit for circuit highlights.

Non-Linear Transfer Functions
Current-feedback op amps are particularly useful in non-linear transfer function circuits. Since bandwidth and other key specifications are independent of gain-setting, the dynamic performance is relatively independent of signal level.

In analyzing the circuit, it is useful to identify the three input signal paths that contribute to the output voltage (the 1k\(\Omega\) resistor and the two diode bridges). Each of these paths terminates at the inverting input—a point that is at virtual ground. Due to feedback, the current through the feedback resistor is equal to the sum of these input currents. The output voltage, therefore, is the product of the feedback resistor and the sum of the input currents.

The individual input currents are equal to the input voltage divided by the respective gain-setting resistor. However, in the signal paths containing the bridges, the current follows this linear relationship until it
limits at 12V/16kΩ. This is what leads to the non-linear gain. A more accurate analysis requires that the diode bulk and dynamic resistances be included.

When $V_{out} < V_{in}$, the op amp output swings in the positive direction causing D1 to conduct and the storage capacitor voltage to be charged through the 200Ω isolating resistor. This action continues until $V_{out} = V_{in}$ and equilibrium is established.

Peak Detector

The circuit shown in the next column can capture 50ns pulses over a 20mV to 1.5V input range. The circuit consists of three basic blocks: the op amp and diodes, the storage capacitor and discharge circuit, and the unity-gain buffer. The peak detecting action is caused by the conduction or non-conduction of the two diodes in the feedback loop.

When $V_{out} > V_{in}$, the op amp output swings in the negative direction until D2 conducts and the feedback path is completed and the op amp does not saturate.

Differential Gain and Phase for Composite Video Systems

David Potson
Michael Steffes
Differential Gain and Phase for Composite Video Systems

A critical performance characteristic for composite video systems relates to how well each device in the signal path maintains a constant small signal gain and phase for the relatively low level color carrier at 3.58MHz as the brightness (or luminance) signal is ramped through its allowed range. This is often specified as the differential gain and phase.

Figure 1 shows a typical composite video signal. The low frequency ramping shown in the test signal controls the brightness of the picture, while the 3.58MHz color carrier (or chrominance signal) riding on top of this controls the color. The amplitude of this carrier controls the color saturation while the phase shift of the carrier relative to the color burst sync. controls the hue. Any non-linearities in a device's gain or phase response as the luminance level is changed will show up as a distortion in the picture color. Note that the amplitudes shown on Figure 1 are those required at the load end of a doubly terminated 75Ω transmission line.

![Figure 1](image)

An amplifier's output DC level can have a profound effect on its small signal response. This is especially true for composite video signals when several parallel doubly terminated 75 ohm loads are driven from a single amplifier output causing the current to vary widely over the luminance range.

Differential gain can be defined as either the maximum percentage change in chrominance gain from the luminance black level to its white level or the peak-to-peak percentage gain change over the same luminance range. The peak-to-peak percentage gain change shall be used here.

Differential phase can be defined as either the maximum change in phase shift through a device, in degrees, from the luminance black level to its white level, or the peak-to-peak phase shift change over the same luminance range. The peak-to-peak change in degrees shall be used here.

Conceptually, the gain and phase response through an amplifier element at the chrominance frequency and amplitude is measured as the luminance, or output DC level, is ramped from its black level, typically 0 volts, to its white level, typically .7 volts. The peak-to-peak variation in the measured gain and phase is taken as the differential gain and phase of the device under test.

Although the perceptible level for differential gain and phase errors are well over the 1% and 1° levels, respectively, the cumulative errors of cascaded video channel devices are calling for individual amplifier errors to be well below the perceptible level. The traditional means of measuring differential gain and phase using a vector scope and/or waveform monitor allow measurements to be made down to approximately the .2% and .1° level. This level of resolution is inadequate for amplifiers intended for today's higher performance test and video distribution equipment. An alternative means of measuring this critical performance parameter using a network analyzer will be described.

Differential Gain and Phase Measurements Using a Network Analyzer

Using the self-calibration feature commonly available in network analyzers, exceptionally fine resolution of gain and phase changes from a reference trace can be determined. Figure 2 shows the overall test configuration used to measure several of the Comlinear amplifiers for differential gain and phase. Although a Hewlett-Packard 4195 spectrum/network analyzer was used to perform these measurements, as well as specific splitters, attenuators, and reflection/transmission test set, equivalent hardware configured to achieve the same result would, of course, be acceptable. The stand-alone programming capability of the HP4195, especially for the built-in DC bias source, make it particularly suitable for differential gain and phase testing. The 4195 has the capability of using the internal DC bias source as the independent variable for setting up its display trace, precisely the capability required for these tests.
Figure 3 shows a typical configuration for the Device Under Test (DUT). The end goal for setting up the DUT stimulus is to generate at the output pin of the amplifier a 0 to 1.4V low-frequency ramp with a .56Vpp 3.58MHz sine wave riding on top of it. This will generate the amplitudes of Figure 1 at the load if we were driving a doubly terminated line. The peak-to-peak change in gain and phase for S21 measured over the DC input sweep, when corrected by a reference trace taken with the DUT replaced by a short, will yield a measure of the differential gain and phase.

Typical DUT Configuration

![Diagram of DUT Configuration]

Note that although the test waveform of Figure 1 shows an entire luminance staircase sweep from white to black in less than 63µsec, the 4195 will generate a considerably slower sweep to allow adequate S21 measurement time at each DC voltage setting. In doing the test this way, we are assuming that no additional device limitations will be encountered in increasing the luminance rate of change to that required by the most demanding video signals. This translates into a requirement for excellent amplifier pulse response which in turn implies adequate slew rate and broadband frequency response flatness (to limit pulse overshoot and ringing). An assessment of an amplifier’s pulse response should be made independently to confirm that its response to slowly varying luminance levels is representative of that to the most rapidly varying signal.

Returning to Figure 2, each element of the test configuration will be described. Since we need to make a network analyzer measurement of a forward transmission characteristic, an S21 measurement, a reflected wave measurement must be made using a reflection/transmission test set. Many network analyzers have this built into their S-parameter test set. To minimize the reflected signal, a good 50Ω match is desired looking out of the R/T test set. Hence, the DC source and the DUT input are made to look like 50Ω on the other side of the power combiner. To minimize any receiver DC sensitivity, AC coupling is used to isolate the RF measurement paths.

The CLC400 is used to buffer the programmable DC source for two reasons. First, the source by itself does not have the current capability to drive the 100Ω load over the needed voltage range and, secondly, the CLC400 provides a more well-defined AC source impedance looking back into its output than the DC control output of the HP4195.

The power combiner provides a means of adding the desired AC and DC signals while maintaining a 50Ω matched environment. There is a 6dB loss for the AC signal through the splitter to the 50Ω DUT input impedance. With the AC coupling present at the 3.58MHz signal input to the splitter, there is, however, only a 3dB loss for the DC signal from the 4195 DC output pin to the 50Ω DUT input. Note that with the CLC400 buffer set up for a gain of 6dB, there is a net gain of 9dB from the CLC400 input to the splitter input and then a 3dB loss from there to the DUT input.

Turning now to Figure 3, the non-inverting input impedance is set to 50Ω to provide good matching to the power combiner output. For the low gain amplifier parts tested, the gain is set to +2 with Rg = Rf and the input attenuator is not required. For the higher gain parts, operated at a linear gain of +20 (10x the low gain), a 20dB attenuator is used with the same DC sweep voltages and rf signal power to achieve the desired sweep at the output. The desired test voltage swings shown on Figure 3 at the output of the amplifier are double those shown on Figure 1 to account for the 6dB loss seen at the load in driving doubly terminated video transmission lines. The 100Ω series output resistor into the 50Ω 14dB attenuator provides the single load case of 150Ω while providing a good 50Ω source impedance to the network analyzer receiver input. Additional loading is simulated by connecting parallel 150Ω resistors to ground directly on the amplifier’s output pin.

To make a differential gain and phase measurement for a particular part type, the DUT (including the 100Ω series output resistor, the input attenuator, and the 50Ω termination) is replaced by a short. Multiple DC voltage sweeps are then taken with the measured gain and phase averaged to develop a reference gain and phase flatness for the test configuration without the DUT in place. Replacing the DUT into the circuit and averaging multiple gain and phase measurements over the DC voltage sweep and subtracting the reference trace data from this will yield the gain and phase flatness for the device. Note that the absolute measured S21 will change going from the calibration to the DUT due to the 100Ω series output resistor. The absolute measured phase will also change due to the increased path length with the DUT in place. Except for non-linearities in the receiver, this won’t matter since we are really only looking at the deviation from flatness for the corrected gain and phase measurements.

After performing the calibration, an example of which appears in Figure 4 with the gain shown in dB, a corrected measurement for the same short will yield a measure of the system resolution. This appears on Figure 5 and shows an approximate gain flatness resolution of .008% and a phase flatness resolution of .005°. These numbers result from taking twice the peak-to-peak variation shown in Figure 5 as an approximate measure of resolution. Note in Figure 4, the uncorrected calibration sweep, that while the gain appears fairly constant over the DC sweep, there is a relatively significant phase change of almost .02°. One possible source for this would be the slight change
in the impedance matching looking into the DC bias source out of the splitter, causing a slight change in the phase shift through the splitter. At any rate, using this data to correct the DUT measured data improves the resolution to the levels listed above. These resolution levels are considerably better than those achievable with a vector scope or a waveform monitor.

CLC400 DC buffer amplifier shown in Figure 2 will need to be run with +6V positive supply to accommodate the +4V output swing required for the CLC110 test. Although not shown on the DUT drawings, each test circuit included the recommended supply decoupling elements shown on that part's data sheet.

The CLC400, a monolithic amplifier optimized for low gain, showed the best overall differential gain and phase. With a single 150Ω load, the peak-to-peak gain variation was .03% while peak-to-peak phase variation was .02°. These are well above the system resolution levels but would present a considerable challenge measurement to a vector scope and/or a waveform monitor.

Measurement Results

Several amplifiers in Comlinear’s product line seem particularly appropriate for composite video distribution. All of the products would actually show excellent differential gain and phase response at the 3.58MHz color carrier due to their exceptionally broad bandwidth and symmetric topologies. (Most devices utilize a Class AB output stage yielding excellent distortion relative to a Class A stage.)

The parts selected for testing included three low cost/size monolithic parts and a low gain hybrid amplifier. The DUT topologies used and the gain and phase plots vs. DC voltage for no additional loading attached (representing a single 150Ω load) are shown in Figures 6 through 10. The required stimulus levels for all of these tests, except the unity gain CLC110, was a DC sweep from 0 to .98V and an RF level = 7.8dBm. Both of these must be doubled to generate the desired output levels for the CLC110.
The CLC401 is a monolithic amplifier optimized for higher gains. Tested at a linear gain of $\pm 20$, a 20dB attenuator is required to use the same stimulus levels into the DUT to produce the desired output swing. At a load of 150Ω, the peak-to-peak gain variation was .02% while peak-to-peak phase variation was .11°.

The CLC110 is a monolithic unity gain buffer with exceptional bandwidth and pulse response. The stimulus levels used for the CLC400 were doubled, both AC and DC, since this DUT has one-half the gain of the CLC400. With the nominal test load of 150Ω, the peak-to-peak gain variation was .17% while the peak-to-peak phase variation was .01°. Compared to the CLC400, this part offers better differential phase but poorer differential gain performance.

The CLC231 is a hybrid amplifier optimized for low gains. It also has the capability of operating at supplies down to $\pm 5V$ with almost full AC performance if the two ladj pins are shorted to their respective supplies. The performance, however, is very poor relative to the CLC400. It was anticipated that the higher slew rate and output current capability of this hybrid part would enhance performance. It appears, however, that even in the single 150Ω case the differential gain is .09% while the differential phase is .14°.
Operating the CLC231 at its recommended ±15V supplies, being careful to remove the shorts to the Iadj pins, yields excellent performance. At the nominal load of 1500Ω, peak-to-peak gain variation was 0.03% and peak-to-peak phase variation was 0.08°. This compares very well to the CLC400 and may actually offer better performance for very high-speed luminance signals due to the higher slew rate offered by the CLC231.

All of the parts tested here offer slew rates in excess of 400V/μsec as well as excellent high-speed pulse fidelity. Increasing the luminance staircase rate to that used in actual composite video signals should have no effect on the differential gain and phase performance.

Figures 11 and 12 show the differential gain and phase vs. number of 150Ω loads for the five sets of tests performed here. Generally, for low gain applications, the CLC400 appears to yield the best overall performance for multiple loads. The CLC401 can be used successfully driving a limited number of loads in those cases where significant gain is required (as in receiving a signal on an exceptional length of cable). The CLC110 can offer some advantages in the differential phase performance if that is the key performance parameter. The CLC231 would be considered at ±15V supplies where multiple lossy lines need to be driven and the loss can be recovered by driving higher output levels at the CLC231 than achievable with the ±5V monolithic parts.
Noise Analysis for Comlinear's Op Amps

Michael Steffes
Abstract: This application note develops the various descriptions of noise used by the industry and applies these terms to Comlinear's current feedback amplifier product line. In addition, a summary table of the equivalent input noise voltage and currents for the amplifiers available from Comlinear at the time of publication is also included (Appendix II). Finally, noise computational aids for analyzing the effect of 1/f noise and converting from small signal -3dB bandwidth to noise power bandwidth is included as Appendix I.

Understanding different descriptions of noise:
Probably the most perplexing aspect of noise analysis is the myriad of descriptions used by the industry for the same underlying phenomena. Different needs lead engineers into describing noise in many different ways. A few of these options are
1. Spot or integrated noise
2. Input or output referred noise
3. Noise powers or noise voltages and currents
4. Noise figure and/or noise temperature

Which form is used for each of these selections depends on what you are trying to accomplish. Spot noises are almost always used in calculating total noise since there is normally a common system bandwidth that will determine the integrated noise. Input noise is of interest for developing the input Signal/Noise ratio while output noise, especially integrated noise, is of interest when comparing the noise level to the ½ LSB of an A/D converter. Computations for developing equivalent noises considering multiple noise sources are always done by combining the powers and power gains, whereas the separate contributing noise sources are almost always defined in terms of currents and voltages. Noise figure and noise temperature are amplifier input noise descriptions common to the RF and communications field.

An example computational flow will illustrate how these various descriptions fit together. Taking the equivalent input spot noise voltages and currents as the starting point for any description of noise (see Figure 1), an equivalent output spot noise power may be computed by taking each voltage and current to the output through its appropriate gain and combining them as the sum of squared terms. Noise current terms always include an impedance in their gain expression to get all terms into squared voltage expressions. Strictly speaking, we should be developing these powers across some resistance. However, in all subsequent expressions the resistances drop out and we are left dealing with voltages, currents, and gains squared. In general, the separate noise sources are taken to be uncorrelated which is why we can combine them by simply adding their component powers. Having computed the total output noise power, the equivalent output spot noise voltage is obtained by taking the square root of this expression.

From this spot noise voltage at the output, all other noise descriptions may be derived. The integrated output noise voltage is obtained by multiplying the spot noise by the square root of the noise power bandwidth. (See Appendix I for a description of the Noise Power Bandwidth (NPB)). This yields an rms noise voltage at the output for that bandwidth. Taking this voltage times 6 will yield the approximate peak-to-peak voltage swing that would be seen on an oscilloscope for this NPB. Adjusting the scope bandwidth illustrates the importance of noise power bandwidth quite well.

Equivalent input spot noise voltages can be derived by taking this output spot noise voltage and dividing by the voltage gain (from whatever input point you wish to define) to the output. This is normally called input referring the output noise. Again, multiplying by the noise power bandwidth will yield the input referred integrated noise. This is normally left as an rms value (as opposed to a peak-to-peak noise). With an equivalent input noise voltage derived, the Noise Figure is developed by comparing this amplifier contributed noise to the source resistor noise.

In general, remember that computations combining noise sources together must be done with squared voltages, currents, and gains. Getting back to voltage or current is simply the square root of the sum of squared terms expression. Integrated noise is computed by multiplying noise power bandwidth (NPB) by the spot noise power (the sum of squared terms), or by multiplying the square root of the NPB by the noise voltages or currents.

Comlinear amplifier noise analysis:
For devices as flexible as Comlinear's current feedback op amps, one of the primary goals in specifying the noise is to do so in a fashion that provides enough information to predict the noise performance under any set of operating conditions. The best way to do this is to define an equivalent non-inverting input noise voltage and input noise currents for the non-inverting and inverting inputs. These are defined as spot noise voltages and currents over frequency, although in most applications, only the relatively constant high frequency (flatband) value is of any interest. These three terms form the most elemental of common denominators for the remaining types of noise descriptions. In any real measurement or application the resistors used to operate the amplifier correctly will also contribute noise. Although often neglected, these can make a significant noise contribution in some cases and must be considered for any complete noise analysis.

![Figure 1](image-url)

Figure 1 shows a non-inverting amplifier configuration with every noise source specified.
With all of the contributing noise sources defined, an output spot noise voltage may be found by using superposition for each of those sources. As with any other linear analysis, each noise source is considered separately by opening all other noise current sources and shorting all other noise voltage sources. Each source's contribution to the output noise is taken as the voltage squared generated by that source at the output. Figure 2a shows the contribution to the output of the noise sources appearing at the non-inverting input.

\[ e_{o1}^2 = \left[ e_n^2 + (i\text{bn} R_T)^2 + 4kT R_T \right] \left( 1 + \frac{R_f}{R_g} \right)^2 \]

where
- \( k = \text{Boltzman's constant} = 1.38 \times 10^{-23} \text{J/K} \)
- \( T = \text{Kelvin} \)
- \( 4kT = 16 \times 10^{-21} \text{Joules at } T = 290^\circ\text{K} \)

**Figure 2a: Non-inverting noise sources**

Note that we are assuming an infinite input impedance at the non-inverting node. This yields a gain of 1 to the non-inverting input for each voltage noise source and a gain of \( R_f \) for the non-inverting current noise. Each of these is squared and referred to the output by multiplying by the non-inverting voltage gain squared.

Figure 2b shows the output noise power contributions for the noise terms on the inverting side of the amplifier circuit.

\[ e_{o2}^2 = \left[ \left( i\text{b} R_f \right)^2 + 4kT R_f \right] \left( 1 + \frac{R_f}{R_g} \right)^2 \]

Combined resistor noise power = \( 4kT R_f \left( 1 + \frac{R_f}{R_g} \right) \)

then, \( e_{o2}^2 = \left( i\text{b} R_f \right)^2 + 4kTR_f \left( 1 + \frac{R_f}{R_g} \right) \)

**Figure 2b: Inverting noise sources**

With no signal at the non-inverting node, the inverting node is taken to be at 0 volts. We assume that the inverting input draws no current, (for current feedback amplifiers the loop gain drives it to 0 while for voltage feedback amplifiers the inverting node presents a high input impedance). With 0 volts across \( R_g \), and no current into the inverting input, the two current noise sources must simply flow through \( R_f \) to appear at the output as voltages. Similarly, with 0 volts at the inverting node and no current path, the noise voltage of \( R_f \) appears as a voltage rise from zero to the output.

These two expressions for the component parts of the output noise power may now be combined for the total output noise power.

\[ 1 + \frac{R_f}{R_g} = A_v, \text{ non-inverting voltage gain} \]

Output noise power, \( e_o^2 \), is then:

\[ e_o^2 = e_{o1}^2 + e_{o2}^2 = \left[ e_n^2 + \left( i\text{bn} R_T \right)^2 + 4kT R_T \right] A_v^2 + \left( i\text{b} R_f \right)^2 + 4kT R_f A_v \]

Output noise voltage is then:

\[ e_o = \sqrt{e_{o1}^2 + e_{o2}^2} = \sqrt{\left[ e_n^2 + \left( i\text{b} R_T \right)^2 + 4kT R_T \right] A_v^2 + \left( i\text{b} R_f \right)^2 + 4kT R_f A_v} \]

This yields a total output voltage noise per \( \sqrt{\text{Hz}} \).
From this spot output noise voltage, all other descriptions of noise may be derived. The integrated output noise, or rms noise voltage in a given noise power bandwidth, can be derived by taking this spot output noise voltage times the square root of the noise power bandwidth (NPB). See Appendix I for an additional discussion of NPB.

Integrated output noise
\[ e_{o(rms)} = e_o \cdot \sqrt{NPB} \]

peak-to-peak output noise voltage
\[ 6 \cdot e_{o(rms)} = 6 \cdot e_o \cdot \sqrt{NPB} \]

Having the rms output noise voltage, the peak-to-peak noise is taken to be 6 times this as a very conservative limit. (Reference 1, page 299)

The input spot noise is simply the output spot noise voltage divided by the voltage gain.

If the input is defined to be at the non-inverting input we would divide by \( A_v = 1 + \frac{R_f}{R_g} \).

Input spot noise voltage, \( e_i \)

\[ e_i = \frac{e_o}{A_v} = \sqrt{e_n^2 + (ibn R_T)^2 + 4kTR_T + \left( \frac{i_{bn} R_f}{A_v} \right)^2 + \frac{4kT R_f}{A_v}} \]

Again, this could be converted to both integrated and peak-to-peak swing as described for the output spot noise voltage. Note that since the final two terms under the radical contribute to the output noise independently of the desired signal gain, as that gain is increased, their impact on the equivalent input noise is reduced. In general, every measure of noise (except the separated component spot noise terms) is strongly dependent on the selection for the value of the feedback resistor and the desired signal gain setting. Thus, data sheet specifications for equivalent noise levels apply only for the test or specification setting used. Additionally, since the feedback resistor value plays such a large role in setting the frequency response for current feedback amplifiers, it cannot be set arbitrarily low to reduce the noise, and should be increased from its recommended value only while recognizing the impact this will have in the noise gain for the inverting current noise term.

The signal noise floor (SNF; specified in the data sheet specs) is simply the input spot noise voltage measured as a power into 50 ohms referenced to 1 mW. Basically, it is the input spot-noise voltage converted to dBm.

\[ \text{SNF} = 10 \log \left( \frac{e_{ni}^2}{50 \cdot 0.001 \ W} \right) = 10 \log 20 + 20 \log e_{ni} \]

\[ \text{SNF} = (13.01 + 20 \log e_{ni}) \text{dBm} \]

The Noise Figure compares the power ratio of input signal/noise ratio to the output signal/noise ratio. One difference with the noise figure description is that the source resistor (\( R_s \)) must be included in the analysis. The input noise is taken as the noise power delivered to the input from the source resistor. The source noise is the total noise power at the output, including the source resistor noise, where gain for the non-inverting input noise current and terminating resistor noise include the presence of \( R_s \). After manipulating the fundamental noise figure expression, it will reduce to \( 10 \cdot \log(1 + e_o/e_s) \) where \( e_o \) is the input noise power (including \( R_s \) in the gain for the current noise), but excluding its noise power, and \( e_s \) is the input noise power due to the source resistor and excluding all other sources (see Application Note OA-11 for a more complete analysis).

With an arbitrary \( R_T \), Figure 3 shows how \( R_s \) will affect the calculation for the equivalent input noise power and what noise power the source resistor will deliver to the input. Comparing this to the earlier expression shows that the \( R_i \) and \( \text{ibn} \) noise current gains are reduced by the parallel addition of \( R_s \).

Input noise power definition point

\[ NF = \frac{10 \log(1 + e_{ni}^2)}{10 \log \left( \frac{i_{bn}^2 + 4kT R_T}{R_s} \right) + e_{n_i}^2 + \left( \frac{i_{bn} R_f}{A_v} \right)^2 + \frac{4kT R_f}{A_v} + \left( \frac{i_{bi} R_f}{A_v} \right)^2 + \frac{4kT R_f}{A_v}} \]

Figure 3

Taking these two expressions for the total input noise power due to the amplifier, \( e_{ni} \) and the input noise power due to the source resistor, \( e_s \), the noise figure expression may be developed.

\[ NF = 10 \log \left( 1 + \frac{e_{ni}^2}{e_s^2} \right) \]
\[ NF = 10 \log \left[ 1 + \left( \frac{i_{bn}^2 + 4kT R_T}{R_s} \right) + e_{n_i}^2 + \left( \frac{i_{bi} R_f}{A_v} \right)^2 + \frac{4kT R_f}{R_s} \right] \]

\[ \left( \frac{i_{bi} R_f}{A_v} \right)^2 + \frac{4kT R_f}{A_v} \]
Letting the input termination resistor, \( R_t \), equal the source resistor (a very common situation where impedance matching is desired) simplifies this noise figure expression as follows:

\[
NF = 10 \log \left[ 1 + \left( \frac{i_{bn} R_s}{2} \right)^2 + kT R_s e_n + \left( \frac{i_{bl} R_t}{A_v} \right)^2 + \frac{4kT R_t}{A_v} \right]
\]

with \( R_T = R_s, \) \( R_T = R_t \) and

\[
NF = 10 \log \left[ 1 + \left( \frac{i_{bn} R_s}{2} \right)^2 + kT R_s e_n + \left( \frac{i_{bl} R_t}{A_v} \right)^2 + \frac{4kT R_t}{A_v} \right]
\]

Conceptually, the 2 factor arises because we are taking a signal division by 2 at the input with a discrete (noisy) terminating resistor, while the remaining ratio is simply a comparison of the equivalent input noise power (excluding the source and terminating resistor noises) to the noise power delivered from the source resistor.

**Example Calculations:**

Let us now use the input spot noise terms for a pair of amplifiers (obtained from Appendix II) to develop each of these descriptions of noise.

Considering the CLC400 and CLC401 in their specifications test circuit:

![CLC400 Circuit Diagram](image)

\[ A_V = +2 \]
\[ e_n = 2.5nV/\sqrt{Hz} \]
\[ i_{bn} = 3.2pA/\sqrt{Hz} \]
\[ i_{bi} = 14pA/\sqrt{Hz} \]

\[
e_o^2 = \left( 2.5nV \right)^2 + \left[ 3.2pA(25\Omega) \right]^2 + \left( 63nV \right)^2 \]
\[
e_o^2 = \left[ 14pA(25\Omega) \right]^2 + 4kT(25\Omega) \]

\[
e_o = \sqrt{e_o^2 + e_o^2} = \sqrt{5.18nV^2 + 4.5nV^2} \]
\[
e_o = 6.8nV/\sqrt{Hz} \]

Integrated output noise with \( NPB = 200\text{MHz} \)

\[ e_o \text{ (rms) } = 5.2nV/\sqrt{200\text{MHz} } = 96.8\mu V_{\text{rms}} \]

Peak - Peak output noise voltage

\[ e_o(p-p) = 6 \times 96.8\mu V_{\text{rms}} = .58\mu V \]

Input integrated noise

\[ e_{ni}(\text{rms}) = \frac{e_o(\text{rms})}{A_v} = \frac{73.5\mu V}{2} = 48.4\mu V \]

This agrees well with the data sheet typical spec. of \( = 50\mu V \)

Equivalent input spot noise voltage

\[ e_n = \frac{e_o}{A_v} = \frac{6.8nV/\sqrt{Hz}}{2} = 3.4nV/\sqrt{Hz} \]

Input Signal Noise Floor (1Hz Band)

\[ SNF = 13.01 + 20\log (e_n) = -156.4\text{dBm} \]

Approximately equal to the data sheet typical spec. of \( -156\text{dBm} \)

Integrated input Noise Floor is \( SNF + 10\log(NPB) \)

Noise Figure with \( R_s = R_t = 50\Omega \)

\[ NF = 10 \log \left[ 2 + \frac{\left[ (3.2pA)(25\Omega) \right]^2 + (2.5nV)^2 + \left[ 14pA(25\Omega) \right]^2}{2} \right] \]

\[ + \frac{4kT(25\Omega)^2}{kT(50\Omega)} \]

\[ NF = 17.7\text{dB for the CLC400} \]

![CLC401 Circuit Diagram](image)

\[ A_V = +20 \]
\[ e_n = 2.4nV/\sqrt{Hz} \]
\[ i_{bn} = 2.6pA/\sqrt{Hz} \]
\[ i_{bi} = 17pA/\sqrt{Hz} \]

\[
e_o^2 = \left( 2.4nV \right)^2 + \left[ 2.6pA(25\Omega) \right]^2 + 4kT(25\Omega) \]

\[
e_o^2 = \left[ 17pA(1500\Omega) \right]^2 + 4kT(1500\Omega) \]

\[
e_o = \sqrt{e_o^2 + e_o^2} = \sqrt{49.7nV^2 + 33.6nV^2} \]
\[
e_o = 60nV/\sqrt{Hz} \]
Integrated output noise with 
NPB = 150MHz 

e_0 (rms) = 60nV\sqrt{150MHz} = .73mV_{rms} 
Peak - Peak output noise voltage 

e_0 (p-p) = 6 \cdot 735\mu V_{rms} = 4.4mV 
Input integrated noise 

e_{inl} (rms) = \frac{e_0 (rms)}{A_v} = \frac{735\mu V}{20} = 36.8\mu V 
this agrees well with the 
the data sheet typical spec. 
of 35\mu V 
Equivalent input spot noise voltage 

e_s = \frac{e_0 (rms) \omega \sqrt{Hz}}{20} = 3.0nV/\sqrt{Hz} 
Input Signal Noise Floor 
(1Hz Band) 
SNF = 13.01 + 20\log(e_n) 
= -157.4dBm 
Approximately equal to the 
the data sheet typical spec. of 
-158dBm 
Integrated input Noise 
Floor is SNF + 10log(NPB) 
Noise Figure with 
R_s = R_t = 50\Omega 

NF = 10 \log \left[ 2 + \frac{[(2.8pA)(25 \Omega)]^2 + (2.4nV)^2}{2 + \frac{(17pA)(1500\Omega)^2}{20} + \frac{4kT(1500\Omega)}{20}} \right] 

NF = 16.5dB for the 
CLC401 

Conclusions: 
With the techniques described here and the data of 
Appendix II, any of the commonly used noise descriptions may be developed. Note that the noise figures developed in the example for the CLC400 and 
CLC401 are rather high, resulting from a relatively high 
equivalent input noise voltage. As described in 
Application Note OA-11, noise figure will decrease as 
the gain is increased and is in fact lower for inverting vs. non-inverting configurations above a certain gain 
unique to each part. Conversely, taking a part intended 
for high gains, such as the CLC401, and operating it 
at low gains will always yield much higher input noises 
and noise figures than a corresponding part intended 
for low gains. This results from the requirement that 
the feedback resistor (the gain term for the inverting 
are higher for higher gain 
parts using the current feedback topology.

A technique for reducing the noise figure by using an 
input transformer is described in Application Note OA-14 ("Improving Amplifier Noise Figure for High 3rd Order 
Intercept Amplifiers").

Circuits" Gray and Meyer

Appendix I.

Including 1/f and Noise Power Bandwidth Effects 
For signal processing applications that are bandlimited 
in such a way as to include the 1/f noise region as a 
significant part of the total NPB, the increase in noise 
seen at low frequencies and modeled as a 1/f increase in 
the equivalent input noise terms, must be 
considered. The discussion that follows will focus on 
the non-inverting voltage spot noise term, although 
similar considerations must be applied to the two 
current noise terms for a complete analysis.

If we consider the total input spot noise power to be 
the sum of a constant flatband value and a frequency- 
dependent term, we can write 

e_s^2 = total input spot noise power 

e_s^2 = e_n^2 + e_s^2 f 

where e_s is unknown 
and f = frequency in Hz 
and e_n = flatband spot noise voltage 

At some frequency we can observe that the total 
equivalent input noise power has doubled. Hence, at 
this frequency the two power contributions are equal. 
Given this frequency, 

f_{3dB} = frequency at which spot noise power has 
doubled from the flatband value, or the spot 
voltage noise has increased \sqrt{2} 

2e_n^2 = e_n^2 + e_{3dB}^2 \frac{e_n^2}{f_{3dB}} 

then, e_T^2 = e_n^2 + \frac{e_{3dB}^2}{f_{3dB}} , e_T^2 = e_n^2 (1+ \frac{e_{3dB}^2}{f_{3dB}}) 

and e_T = e_n \sqrt{1+ \frac{e_{3dB}^2}{f_{3dB}}} spot noise voltage including 
the 1/f noise region 

If the spot noise expressions are of interest, this 
adjustment to the reported flatband values in Appendix 
II, along with the 1/f noise corner frequency, should be 
used at frequencies near or below the f_{3dB} frequency. 
If the noise integrated over a particular frequency range 
is of interest, it is best to develop an equivalent spot 
noise voltage over that frequency range first, and then 
multiply by the square root of the NPB. This equivalent 
input spot noise, including 1/f effects, is developed as 
the average noise power over that frequency range 
using the spot noise expression developed above.

11 - 38
\[ e_{eq}^2 = \frac{1}{f_2 - f_1} \left( f_2^2 + f_1^2 \right) \int_{f_1}^{f_2} \frac{df}{1 + \frac{f_{3dB}}{f}} \]

or, going back to equivalent spot voltage

\[ e_{eq}^2 = \frac{e_n^2}{f_2 - f_1} \left( f_2^2 + f_1^2 \right) \int_{f_1}^{f_2} \frac{df}{1 + \frac{f_{3dB}}{f_1}} \ln \left( \frac{f_2}{f_1} \right) \]

Note that \( f_1 \) cannot be 0 in this expression. To evaluate the expression, use an arbitrarily low \( f_1 \) for DC coupled applications, typically 10Hz. Also note that this adjustment to the flatband \( e_{ni} \) is increasingly insignificant as \( f_2 \) extends well above \( f_{3dB} \). The table below computes the adjustment factor to the flatband noise as the upper cutoff frequency \( f_2 \) is extended beyond the \( 1/f \) noise corner \( f_{3dB} \).

Using the equivalent spot noise voltage (and currents), the integrated noise may be determined using the noise power bandwidth. For a given voltage transfer function over frequency, the NPB is that rectangular frequency span that encloses the same power as the network's frequency response (Reference 1). The relationship between the more commonly specified -3dB bandwidth and the noise power bandwidth depends on the response shape. For the single pole low pass response, the relationship is

\[ H(s) = \frac{W_0}{s + W_0} \text{ where } f_{-3dB} = \frac{W_0}{2\pi} = \text{-3dB point} \]

\[ \frac{\text{NPB}}{f_{-3dB}} = 1.57 \]

For a single pair of complex poles acting as a low pass filter,

\[ H(s) = \frac{W_0^2}{s^2 + \frac{W_0}{Q} + \frac{W_0^2}{2\pi}} \]

\[ f_{-3dB} = \frac{W_0}{2\pi} \sqrt{\left( 1 - \frac{1}{2Q^2} \right) + \left( 1 - \frac{1}{2Q^2} \right)^2} + 1 \]

\[ \frac{\text{NPB}}{f_0} = Q \frac{\pi}{2} \text{ where } f_0 = \frac{W_0}{2\pi} \]

Comlinear's current feedback amplifiers are designed to have a \( Q = .707 \) at the gain and \( R \) value listed at the top of each part's specifications table. With \( Q = .707 \), the closed loop poles are at \( \pm 45^\circ \) to the negative real axis (in the s-plane) and a maximally flat Butterworth response is achieved. Using \( Q = .707 \), and noting that \( f_{-3dB} = f_0 \) for this \( Q \),

\[ \frac{\text{NPB}}{f_{-3dB}} = 1.11 \text{ (this agrees with Reference 2, page 660)} \]

For higher order filter responses, the NPB approaches the -3dB bandwidth. If a filter follows the amplifier, the NPB of the filter should be used.

### Appendix II.

#### Input Spot Noise Component Terms for Comlinear Amplifiers

Listed below are the separate input noise terms measured for the family of both monolithic and hybrid amplifier products. These are defined as:

- \( e_n = \text{Non-inverting input noise voltage in nV/\sqrt{Hz}} \)
- \( i_{bn} = \text{Non-inverting input noise current in pA/\sqrt{Hz}} \)
- \( i_{bn} = \text{Inverting input noise current in pA/\sqrt{Hz}} \)

(Also refer to Figure 1 in the noise analysis description)

The values reported represent the average measured for that term from 1MHz to 10MHz (note that the powers are averaged, then the voltage or current derived as the square root of that average power). 1MHz is generally above any 1/f effects while 10MHz is below any response rolloff effects for the amplifiers under test. The flatband region of performance is assumed to extend beyond 10MHz.

The reported flatband spot noise values are very consistent for a particular amplifier from part to part. The 1/f noise corner frequencies are consistently lower, and more consistent from part to part, for the hybrid amplifiers as opposed to the monolithic amplifiers. Variations in the 1/f noise corner frequencies have been observed for the monolithic amplifiers with the reported number an estimate of the typical and 10kHz a good measure of the maximum for most of the monolithic amplifiers. As described in Appendix I, for most broadband applications, the flatband value will dominate the overall noise performance with the 1/f corner location of secondary importance.

In some cases, the numbers reported here do not agree with those in the individual data sheets. Some of the earlier data sheet noise numbers were extracted from measured data neglecting the effect of the resistor noises. As described in the noise analysis, this can sometimes lead to significant errors.
The separated noise terms reported here should take precedence over those reported in the data sheet for the amplifiers considered.

Current Feedback Amplifier Loop Gain Analysis and Performance Enhancements

Michael Steffes
With the introduction of commercially available amplifiers using the current feedback topology by Comlinear Corporation in the early 1980s, previously unattainable gains and bandwidths in a DC coupled amplifier became easily available to any design engineer. The basic achievement realized by the current feedback topology is to de-couple the signal gain from the loop gain part of the overall transfer function. Commonly available voltage feedback amplifiers offer a signal gain expression that appears identically in the loop gain expression, yielding a tight coupling between the desired gain and the resulting bandwidth. This historically has led to the gain-bandwidth product idea for voltage feedback amplifiers. The current feedback topology transcends this limitation to offer a signal bandwidth that is largely independent of gain. This application note develops the current feedback transfer function with an eye towards manipulating the loop gain.

**Current Feedback Amplifier Transfer Function Development**

The equivalent amplifier circuit of Figure 1 will be used to develop the non-inverting transfer function for the current feedback topology. The current feedback topology is also perfectly suitable for inverting mode operation, especially inverting summing amplifiers. The non-inverting transfer function will be developed, in preference to the inverting, since the inverting transfer function development is a subset of the non-inverting.

![Figure 1: Current Feedback Amplifier Internal Elements](image)

The amplifier's non-inverting input presents a high impedance to the input voltage, V⁺, so as not to load the driving source. Any voltage appearing at the input node is passed through an open loop, unity gain, buffer that has a frequency dependent gain, α(s). α(s) is very neatly equal to 1 at DC (typically .996 or higher, but always < 1.00) and typically has a -3dB point beyond 500 MHz. The output of the buffer ideally presents a 0Ω output impedance at the inverting input, V⁻. It actually shows a frequency dependent impedance, Zᵢ, that is relatively low at DC and increases inductively at high frequencies. For this development, we will only consider that Zᵢ is a small valued resistive impedance, Rᵢ.

The intent of the buffer is to simultaneously force the inverting node voltage to follow the non-inverting input voltage while also providing a low impedance path for an error current to flow. Any small signal error current flowing in the inverting node, ierr, is passed through the buffer to a high transimpedance gain stage and on to the output pin as a voltage. This transimpedance gain, Z(s), senses ierr and generates an output voltage proportional to it. Z(s) has a very high DC value, a dominant low frequency pole, and higher order poles. When the loop is closed, the action of the feedback loop is to drive ierr to zero much like a voltage feedback amplifier will drive the delta voltage across its inputs to zero. Z(s) ideally transforms the error current into a zero ohm output impedance voltage source.

Figure 2 steps through the transfer function development including the effect of Rᵢ. This analysis neglects the impact of a finite output impedance from Z(s) to the output, output loading interactions with that output impedance, and the effect of stray capacitance shunting Rᵢ.

Start by summing currents at the V⁻ node of Figure 1

\[ V₀ - V⁻ = \frac{V₀}{Rᵢ} \quad \text{Eq. 1} \]

We also know that,

\[ V⁻ = \alpha(s) V⁺ + iₜerr Rᵢ \]

and,

\[ \frac{\alpha(s)}{Z(s)} V⁺ = \text{V₀} \quad \text{then,} \quad iₜerr = \frac{\text{V₀}}{Z(s)} \]

Multiply equation 1 through by Rᵢ and isolate V⁻

\[ Rᵢ iₜerr + \text{V₀} = V⁻ \left( 1 + \frac{Rᵢ}{R₀} \right) \]

Now substitute in for iₜerr and V⁻ from above

\[ \frac{Rᵢ}{Z(s)} \frac{\text{V₀}}{\text{V⁺}} = \left( \frac{\alpha(s)}{Z(s)} \frac{\text{V⁺}}{R₀} \right) \left( 1 + \frac{Rᵢ}{R₀} \right) \]

Gather terms and solve for \( V₀ / V⁺ \)

\[ V₀ \frac{\alpha(s)}{V⁺} = \frac{\alpha(s) \frac{1 + \frac{Rᵢ}{R₀}}{Z(s)}}{1 + \frac{Rᵢ + Rᵢ \left( 1 + \frac{Rᵢ}{R₀} \right)}{Z(s)}} \quad \text{Eq. 2} \]

**Figure 2. Current Feedback Amplifier Transfer Function**

It is instructive to consider the separate parts of Equation 2 separately.

\[ \alpha(s) \rightarrow \text{Frequency dependent buffer gain. Normally considered} = 1 \]

\[ 1 + \frac{Rᵢ}{R₀} \rightarrow \text{Desired signal gain. Identical to voltage feedback non-inverting amplifier gain.} \]

\[ \frac{Rᵢ + Rᵢ \left( 1 + \frac{Rᵢ}{R₀} \right)}{Z(s)} = \frac{1}{\text{Loop Gain}} \]
Hence, Loop Gain (LG) = \[ \frac{Z(s)}{R_1 + R_f \left( 1 + \frac{R_f}{R_g} \right)} \] Eq. 3

The loop gain expression is of particular interest here. If \( Z(s) \), the forward transimpedance, is much greater than \( R_1 + R_f \left( 1 + \frac{R_f}{R_g} \right) \), the feedback transimpedance, (as it is at low frequencies) then this term goes to zero leaving just the numerator terms for the low frequency transfer function. As frequency increases, \( Z(s) \) rolls off to eventually equal the feedback transimpedance expression. Beyond this point, at higher frequencies, this term increases in value rolling off the overall closed loop response.

The key thing to note is that the elements external to the amplifier that determine the loop gain, and hence the closed loop frequency response, do not exactly equal the desired signal gain expression in the transfer function numerator. **The desired signal gain expression has been de-coupled from the feedback expression in the loop gain.**

If the inverting input impedance were zero, the loop gain would depend externally only on the feedback resistor value. Even with small \( R_i \), the feedback resistor dominantly sets the loop gain and every current feedback amplifier has a recommended \( R_f \) for which \( Z(s) \) has been optimized. As the desired signal gain becomes very high, the \( R_f \left( 1 + \frac{R_f}{R_g} \right) \) term in the feedback transimpedance can come to dominate, pushing the amplifier back into a gain bandwidth type operation.

Understanding the Loop Gain
It is very useful, and commonly done for voltage feedback amplifiers, to look at the loop gain graphically. Figure 3 shows this for the CLC400, a low gain part offering DC to 200MHz performance. What has been graphed is \( 20 \log|Z(s)| \), the forward transimpedance gain, along with its phase, and \( 20 \log(Z_l) \). This \( Z_l \) is the feedback transimpedance, \( R_1 + R_f \left( 1 + \frac{R_f}{R_g} \right) \), and where it crosses the forward transimpedance curve is the frequency at which the loop gain has dropped to 1. Note that the forward transimpedance phase starts out with a 180° phase shift, indicating a signal inversion through the part, and could have plotted as continuing to 360° or, as shown, going to zero. Using these axes allows a direct reading of the phase margin at unity gain crossover.

As with any negative feedback amplifier, the key determinant of the closed loop frequency response is the phase margin at unity gain crossover. If the phase has shifted completely around to 360°, or dropped to zero on the axis used above when the loop gain has decreased to 1, unity gain crossover - (where the 20 log(\( Z_l \)) line intersects the 20 log(|\( Z(s) |)| curve), the denominator in the closed loop expression will become (1-1), or infinity (For the axis used above, the closed loop expression (Eq.2) would have a 1-1/LG in the denominator. The form developed as Equation 2 accounted for the inversion with the sign convention for \( i_{\text{err}} \) and \( V_o \).

It is critical for stable amplifier operation to maintain adequate phase margin at the unity gain crossover frequency. The feedback transimpedance that is plotted in Figure 3 is \( R_1 + R_f \left( 1 + \frac{R_f}{R_g} \right) \) evaluated at the specifications setup point for the CLC400. This yields:

\[ R_1 = 250\Omega \]
\[ A_p = 1 + \frac{R_1}{R_g} = 2 \]
\[ Z_l = 250\Omega + 50\Omega \quad (2) = 350\Omega \]
\[ Z_l \approx 50\Omega \]
\[ 20 \log (350\Omega) = 50.9 \text{ dB} \]

Looking at the unity gain crossover near 100MHz, we see somewhere in the neighborhood of a 60° phase margin. This is Comlinear's targeted phase margin at the gain and \( R_f \) used to specify any particular current feedback part. This phase margin, for simple 2 pole \( Z(s) \), yields a maximally flat Butterworth filter shape for the closed loop amplifier response (Q=.707). Note that the design targets reasonable flatness over a wide range of process tolerances and temperatures. This typically yields a nominal part that is somewhat overcompensated (phase margin > 60°) at room temperature.

Note that the closed loop bandwidth will only equal the open loop unity gain crossover frequency for 90° phase margins (single pole forward gain response). As the open loop phase margin decreases from 90°, with the impact of higher frequency poles in the forward transimpedance gain, the closed loop poles move off the negative real axis (in the s-plane) peaking the response up and extending the bandwidth. The actual bandwidth achieved by Comlinear's amplifiers is considerably beyond the unity gain crossover frequency due to these open loop phase effects.
Controlling the Loop Gain

One of the key insights provided by the loop gain plot is what happens when $Z_i$ is changed. Decreasing $Z_i$ (dropping the horizontal line of $20 \log(Z_i)$), will extend the unity gain crossover frequency but will sacrifice phase margin. This is commonly seen in current feedback amplifiers when an erroneously low $R_i$ value is used yielding an extremely peaked frequency response. In fact a very reliable oscillator can be generated with any current feedback amplifier by using $R_i = 0$ in a unity gain configuration. Conversely, increasing $Z_i$ (raising the horizontal line of $20 \log(Z_i)$) will drop the unity gain crossover frequency and increase phase margin. Increasing $R_i$ is in fact a very effective means of overcompensating a current feedback amplifier. Increasing $R_i$ will decrease the closed loop bandwidth and/or decrease peaking in the frequency response.

Computing $Z_i$ for the design point used in setting the specifications for any particular current feedback part indicates an optimum targeted feedback transimpedance under any condition.

In design, the internal $Z(s)$ has been set up to yield a maximally flat closed loop response with the gain and $R_f$ used to develop the performance specifications. If we then try to hold the same feedback transimpedance under different gain conditions, an option not possible with voltage feedback topologies, this optimum unity gain crossover for the open loop response can be maintained.

If we designate this optimum feedback transimpedance as $Z_i^*$, we would like to hold $R_i + R_j (1 + R_j / R_i) = Z_i^*$ (where $R_j$ and $1 + R_j / R_i$ are those values shown at the top of the parts performance specifications.)

Substituting $A_v = 1 + R_j / R_i$, we get, $R_i = Z_i^* / R_j \cdot A_v$ \hspace{1cm} Eq. 4

(where $R_i$ is a new value to be used at a gain other than the design point.)

This is a design equation for holding optimum unity gain crossover. Having computed $R_i$ to hold $Z_i = Z_i^*$

$$R_i = R_j / (A_v - 1)$$

\hspace{1cm} Eq. 5

The Benefits of Controlling $Z_i$

As an example of adjusting $R_i$ to hold a constant $Z_i$ as the desired signal gain is changed, consider a CLC404 at gains of +2, +6 and +11. Figure 4 shows test results over these gains for a fixed $R_i$ - very similar to how the CLC404 data sheet plots were generated.

Using the CLC404 design and specifications points (see Appendix I)

$$A_v = +6$$

$$R_i = 500 \, \Omega$$

$$R_j = 30 \, \Omega$$

$$Z_i^* = 500 + 30 \times 6 = 680 \, \Omega$$

Figure 5 shows the same part operated with $R_i$ adjusted as indicated by Equation 4. $R_j$ in both cases is set using Equation 5.

The results of Figure 5 vs. Figure 4 show that adjusting $R_i$ does indeed hold a more constant frequency response over gain than a simple fixed $R_i$. The low gain response has flattened out while the high gain response has been extended.

The remaining variability in frequency response can be attributed to 2nd order effects that have not yet been considered. As described in Application Note OA-15, parasitic capacitance shunting the gain setting resistor, $R_j$, will introduce a response zero for non-inverting gain operation. This zero location can be easily located by substituting $R_j || C_j$ into the numerator part of the transfer function, Equation 2. This yields a zero at $1/(R_j || R_j) C_j$ in radians. This effect would not be observed in inverting mode operation yielding a much more consistent response over gains, especially with $R_j$ adjusted as shown above.

If we assume equal parasitic capacitances on the two inputs, we can cancel this zero by introducing a series impedance into the non-inverting input that equals $R_j || R_j$. Figure 6 shows the test circuit and table of values used.
An alternative to adding $R_i$ is simply to continue to increase $R_i$ until the loop gain is overcompensated enough to cancel the zero. This is increasingly ineffective as the resistor values get larger but was developed empirically for the CLC414 and CLC415 quad amplifiers (Refer to those data sheets for details). An alternative approach with those parts would be to adjust $R_i$ using the data from Appendix I and then add an $R_i$ as described above.

Note that Equation 3 will predict negative $R_i$ values as the desired gain exceeds $Z_i^*/R_i$. From a loop gain standpoint, this is exactly correct. However, additional concerns (particularly distortion and output current limits) will come in to limit the applicable range of gains for Equation 3. Generally, the total loading on the amplifiers should not be allowed to drop below 65 ohms. This is the actual load in parallel with $R_i + R_o$ for the non-inverting configuration. For a 100 ohm load, this limits the minimum $R_i + R_o$ to about 200 Ohm. Lower values can be used if $R_i$ is greater. For inverting mode, which has exactly the same loop gain expression as non-inverting, $R_o$ alone appears in parallel with $R_i$ as an additional load. This would limit $R_i$ to a minimum of 200 Ohm in inverting mode operation. This does not, of course, limit the amplifier's maximum gain. When a minimum $R_i$ has been reached, $R_i$ can continue to decrease, yielding higher gains, with a gain bandwidth characteristic eventually developing as the $(R_i(1+R_i/R_o))$ part of $Z_i$ comes to dominate.

**Special Considerations for Variable Supply Current**

The inverting input impedance, $R_i$, is essentially the output impedance of parallel/series combinations of emitter followers for most CMLinear amplifiers. Thus, $R_i$ is some fraction or integer multiple of $V_i/I_{cc}$, where $V_i = kT/q$ and $I_{cc}$ is the bias current in those transistors. For lower power parts, and parts with adjustable supply currents, $R_i$ can get very large, as $I_{cc}$ decreases quickly putting the parts into a gain bandwidth type operation. Appendix I shows the nominal design point $I_{cc}$, along with a room temperature $R_i$ and, for the adjustable supply current, $I_{cc}$. Anything that adjusts the total quiescent supply current from its nominal design point, changing power supply voltages, using the bias adjust pins on some parts, etc., will scale the $I_{cc}$ listed in Appendix I in direct proportion to $I_{cc}$.

**Additional Loop Gain Control Applications**

Recognizing that the inverting input impedance provides an opportunity to adjust the loop gain, without having any impact on the signal gain, we can add a resistor inside the loop that can act as an independent frequency response compensation element. This is very useful if a fine control over the frequency response shape is desired.

Using the same CLC404 used in the earlier tests (a part that is nominally overcompensated as shown by the rolloff at its gain of +6 condition in Figure 4), the circuit of Figure 8 shows an adjustment technique for the frequency response. Since we are intentionally adding $R_i$, to the feedback transimpedance expression, $Z_i$, it is recommended to approximately set $R_i$ to yield $Z_i^*$ when the
adjustment to $R_j$ is at midrange. This will yield a lower $R_j$ as shown in Figure 8. Figure 9 shows the original gain of +6 response of Figure 4, along with the response achieved with the circuit of Figure 8 with $R_p$ adjusted to yielded maximally flat frequency response. This circuit shows a $\pm .1\text{dB}$ gain flatness to beyond 100 MHz.

**Figure 8: Adjustable Frequency Response**

![Figure 8](image)

**Figure 9**

In inverting applications there is oftentimes a conflict between the required gain setting resistors from an input impedance and signal gain standpoint, and what the amplifier would like to see from a loop gain phase margin standpoint. In a similar fashion to voltage feedback, in this case, an additional resistor to ground on the inverting input can be used to tune the loop gain independently of the inverting signal gain requirements. The drawback of this, is that, like voltage feedback, this increases the noise gain for the non-inverting input voltage noise.

Figure 10 shows an example of a transimpedance application using a CLC401 with a 1kΩ feedback resistor. In this case, the value of the feedback resistor is set by the desired signal gain, while $R_g$ is used to satisfy the loop gain phase margin by setting the feedback transimpedance to $Z_t^* = 2.5k$. Similarly, in an inverting summing application, once the desired gain and input impedance conditions are set, the loop gain can be independently controlled through the use of an additional resistor to ground on the inverting input. Figure 11 shows an example of this using the CLC401 summing 5 channels, at a gain of -1 for each channel, using 1kΩ input resistors.

**Figure 10**

![Figure 10](image)

**Figure 11: Loop Gain Adjusted in inverting Summing Application**

Conclusions

The current feedback topology has allowed us to decouple the signal gain from the loop gain expressions. This provides ample opportunity for independent control of both the signal gains and the frequency response by using only resistive elements. A thorough understanding of the loop gain mechanisms provides the designer with a flexibility unavailable to the voltage feedback op amp.

From Appendix I, for the CLC401

\[
Z_t^* = 2.5k, R_s = 50\Omega \\
50\Omega \left(1 + \frac{R_t}{R_g}\right) = 2.5k \cdot R_f \\
\text{then, } R_g = \frac{1.1k}{1.5k} = 34.5\Omega
\]

With 200Ω || $R_g = 34.5\Omega$ as in Figure 10, this would be satisfied

\[
\text{then, } R_g = 41.7\Omega
\]
Appendix I

The data tabulated here provide the necessary information to hold a constant feedback transimpedance over a wide range of closed loop signals gains for the current feedback amplifiers available from Comlinear at the time of this application note’s publication. The data is broken into a set for the monolithic amplifiers, which generally have a higher \( R_i \) due to their lower quiescent bias current, and a set of data for the hybrid amplifier products.

The table entries show

1. \( A_v \) -> Non-inverting voltage gain used to set device specs.
2. \( R_f \) -> Feedback resistor value used to set the device specs.
3. \( R_i \) -> Nominal inverting input impedance

These 3 items are used to compute the optimum feedback transimpedance for the particular part. This is given by

\[
Z^*_i = R_i + R A_v
\]

This information is used to compute a more optimum \( R_i \) as the desired closed loop gain moves away from the design point \( A_v \).

It is important to note that, given any feedback \( R_f \) and any closed loop non-inverting signal gain, a feedback transimpedance can be computed using the equation for \( Z_i = R_i + R A_v \). \( Z^*_i \) is the optimum value for open loop phase margin and closed loop response flatness found by evaluating the expression at the specific \( R_i \) and gain used in designing and specifying the part.

\( I_c \) -> Approximate collector current for the emitter followers seen looking into the inverting input. The inverting inputs do not necessarily present an integer number of series/parallel emitter followers. The approximate scale factors can be computed by solving for \( n \) in the following expression.

\[
R_i = n \frac{V_i}{I_c} \text{ with } V_i = kT/q (=26mV \text{ at room temperature})
\]

\( I/I_c \) -> ratio of inverting input stage bias current to the total device quiescent current. With \( n \) determined from above, the adjusted value for \( R_i \) may be determined for a part that is being operated at a different quiescent current than is normally specified.

The data presented here represent a good approximation to the device characteristics. Several second order effects have been neglected for the sake of simplicity.

The CLC505, an adjustable supply \( I_c \) op amp, was optimized at 9mA supply current. No attempt was made in this table, or in the data sheet, to reset the optimum \( R_i \) as the supply current is decreased. At very low supply currents, the CLC505’s inverting input impedance dominates the feedback transimpedance expression. To compensate for this with a reduced \( R_i \), as has been suggested in this document, would require such low values as to excessively load the limited output drive current available. The CLC505 at 1mA supply current shows a gain bandwidth product performance due to the dominance of \( R_i \) in the loop gain equation.

### Notes
1. Power supplies at ±15V
2. 25°C temperature assumed; yields $kT/q=.026V$
3. CLC103 & CLC203 have fixed internal $R_f$. Cannot, therefore increase the $R_i$ value or insert additional $R_i$ for loop gain control.
4. These parts include an optional internal feedback resistor that may or may not be used in applying the part. Not using this internal $R_i$ allows adjusting the $R_i$ over gain and/or inserting additional $R_i$.
5. CLC205, CLC206, & CLC207 use a small shunting capacitance across the internal $R_f$ to extend the bandwidth. Using a standard RN55D external $R_f$, with lower shunt capacitance, will require a larger nominal design point value for $Z_t^*$ to hold optimum loop gain. At $A_v=+20$, an external $R_f=2.74 \, k\Omega$ yields the desired $Z_t^*$.
Improving Amplifier Noise Figure for High 3rd Order Intercept Amplifiers

Michael Steffes
Abstract: Wide spurious-free dynamic range is certainly the goal for any IF amplifier. This is particularly true for OTH radar as well as other systems using high resolution digitizers. Recently introduced current feedback amplifiers offer exceptional 3rd order intermodulation intercepts at very low quiescent power levels, but have been plagued by relatively poor noise figures. Teaming these op amps with a simple transformer input coupling yields noise figures less than 7dB with 3rd order intercepts greater than 40dBm (for frequencies < 10MHz).

Although not commonly considered for IF amplifiers, wideband, DC coupled operational amplifiers can offer considerable performance advantages at the lower IF (or HF) over standard AC coupled amplifiers. Particularly suitable from a distortion standpoint are a family of recently introduced monolithic current feedback operational amplifiers. Similar to the more common voltage feedback op amps, these parts offer very high non-inverting input impedance, very low output impedance, and a very high open loop gain that is controlled through the use of external resistors to set a well controlled closed loop gain. These amplifiers are unique in that the inverting node presents a feedback current as opposed to the more common feedback voltage. (Reference 1)

The current feedback topology, as implemented in Comlinear's CLC400 and CLC401 amplifiers, is also exceptionally symmetric. This yields intrinsically low distortion mechanisms internal to the amplifier which are then divided by the loop gain to yield the closed loop distortion. As described in Reference 1, the loop gain for a current feedback amplifier is principally set by the feedback resistor value. The loop gain will, of course, show a frequency dependence yielding a continued improvement in distortion down to the dominant open loop pole frequency (at approximately 350kHz for these parts). Conversely, the distortion will worsen moving to higher frequencies as the open loop gain rolls off. Measuring the 3rd order intermodulation intercept at 10MHz yields between 40 and 45dBm for these two parts. Although theory indicates a continued improvement below this frequency, accurate measurements are difficult to perform for intercepts above 45dBm for output power levels within the capability of these two devices.

Taking advantage of this exceptional intercept performance has, however, been impaired by noise figures ranging from 11 to 20dB depending on the device and the gain setting used. Reflecting all op amp noise sources to the non-inverting input typically yields an equivalent input spot noise voltage (at frequencies above the 1/f noise corner) that range from 2.4nV/√Hz to well over 5nV/√Hz (for the CLC401 operated at low gains.) Aside from the intrinsic noise voltage at the non-inverting input, the effect of the inverting noise current also contributes strongly to this result. (See the appendix and Application Note OA-12 for a discussion of calculating the equivalent input noise voltage.)

As suggested in the literature (Reference 2), transformer coupling can sometimes be used to reduce an amplifier's noise figure. This is possible when the equivalent input noise voltage is much greater than the noise voltage generated by the input noise current through the source impedance. Reference 2 suggests an optimum source impedance for noise figure given by the ratio of noise voltage to noise current. If this ideal impedance is much greater than the typical 50 ohm source impedance seen in IF strips (as it is for the two amplifiers considered here), a significant improvement in the noise figure can be achieved using transformer coupling. Conceptually, the transformer will provide a noiseless voltage gain at the expense of increasing the source impedance for the input noise current.

Using this technique with the current feedback op amps will sacrifice the DC coupling, with the transformer setting the low frequency limit of operation. Depending on the amplifier to set the high frequency limit will yield poor distortion performance near the amplifier's -3dB frequency. The amplifier's -3dB point is largely determined by the frequency at which the loop gain has dropped to unity. With negligible loop gain, the internal distortion mechanisms are no longer corrected yielding poor distortion performance. Hence, it is preferable to have the transformer also limit the high frequency performance. Both amplifiers considered here offer -3dB bandwidths exceeding 100MHz. A transformer offering good performance up through 50MHz maximum and down to as low a frequency as is desired would probably be a suitable choice.

Topology Description

Figure 1 shows the topology to be considered.

The transformer will provide a noiseless voltage gain from the voltage applied to its input to the non-inverting input of the amplifier. This is done at the expense of increasing the AC source impedance looking back out of the amplifier's non-inverting input. Increasing the turns ratio of the transformer (i.e. picking up voltage gain) will decrease the noise figure until the noise term due to the non-inverting input noise current times the source impedance equals the equivalent non-inverting input noise voltage.
Constraints and Assumptions

1. Input impedance matching to the source impedance ($R_s$) at the transformer input is desired. Therefore, $R_1 = n^2 R_s$

   With this assumption, going to the output side of the transformer, the source impedance for the non-inverting input noise current will equal $R_1/2$ or, in terms of $R_s$, will be $n^2 R_s/2$.

   $R_1$ will also introduce a noise voltage term into the analysis.

2. Since the op amp offers a low output impedance, a separate matching resistor must be added to drive into a matched load as would be typical in an IF application (normally, $R_o = 50$ ohms). If we assume the resistor noise of the output matching network is negligible compared to the noise at the output, no change in the S/N ratio will be seen in going from the output pin of the amplifier to the load point. Therefore, the noise figure and gain will be calculated to the load point neglecting any noise added by the output matching resistor, $R_o$.

3. The various noise contributors for the amplifier are considered to be uncorrelated. This allows equivalent total noise powers to be developed as the sum of the separate noise powers. The noise voltage and currents are taken to be the spot noise values yielding a spot noise figure value. For transformer low frequency rolloff corners $< 100$kHz, some increase in spot noises at the low frequencies will be observed due to the 1/f noise corners for the amplifiers. (Refer to the individual op amp data sheets or Application Note OA-12 for detailed noise data).

Noise Figure Computation

To develop an expression of the noise figure for the circuit of Figure 1, the most elementary definition shown as Equation 1 will be used

$$NF = 10 \log \frac{S_i/N_i}{S_o/N_o} \tag{Eq. 1}$$

This definition states that the noise figure is 10 times the log of the ratio of the signal/noise ratio at the input to the signal/noise ratio at the output. These ratios are for the signal and noise powers available at the input and output. The noise power available at the input is taken to be that delivered by $R_s$ to a conjugate matched load where the noise of that load is separated out as being added by the system. Since some noise will always be added, the signal/noise ratio at the output will be degraded from that at the input yielding a noise figure always $> 0$.

To evaluate the noise figure expression, the circuit of Figure 1 is redrawn in a more idealized form in Figure 2.

![Figure 2](image)

In this circuit, the transformer has been replaced by its equivalent elements; an input terminating impedance ($R_o$), a noiseless voltage gain given by the turns ratio ($n$), and an equivalent output impedance taken as the parallel combination of $R_s$ and $R_o$ reflected through the transformer. ($R_1/2$). Note that $R_1$ has been reflected to the input side as a noiseless terminating resistor, $R_s$. $R_s$'s noise contribution is retained as $e_n$ on the output side of the transformer since this needs to be considered as part of the noise added by the system.

The amplifier has been replaced by an infinite input impedance gain block ($A_v$) with its two equivalent noise sources brought out as $e_{n1}$ and $i_{n1}$. Note that $e_{n1}$ includes the noise contribution of the inverting input noise current and the feedback and gain setting resistor noises. (This analysis is described in the appendix.)

Although the gain and noise terms of Figure 2 have thus far been expressed as voltage gains with noise voltage and current terms, the noise figure development deals only with power gains and noise powers. Therefore, the gains and noises shown on Figure 2 will be modified to get the power gain from input to output and the noise powers delivered at the input and output.

Looking at the separate parts of the argument in Equation 1, we can separate them as:

$$S_i \rightarrow \text{inverse of the power gain through the path } S_o$$

$$= \frac{V_i^2/R_o}{(nA_vV_s)^2/R_o} = \frac{4}{(nA_v)^2R_o/R_s}$$

$$\frac{N_o}{N_i} \rightarrow \text{output noise power over input noise power}$$

The output noise power can be developed by taking each contributing noise voltage term through to the output then developing the power of that voltage across $R_o$ and adding all the terms. The separate noise voltage terms at the output are:

- Source noise voltage $\rightarrow \sqrt{4kT R_s} \frac{1}{2} nA_v \frac{1}{2}$
- Terminating resistor noise ($e_t$) $\rightarrow \sqrt{4kT R_s} \frac{1}{2} A_v \frac{1}{2}$

   where $K \rightarrow$ Boltzman's constant $= 1.38E-23$ Joules/Kelvin
   $T \rightarrow ^\circ$Kelvin $= 290^\circ$ in this analysis

   then $4kT = 16E-21$J

- Amplifier current noise $\rightarrow e_{n1} \frac{R_1}{2} A_v \frac{1}{2}$
- Amplifier current noise $\rightarrow e_{n1} A_v \frac{1}{2}$

Note that both noise voltages intrinsic to $R_s$ and $R_1$ are attenuated by 1/2 due to the impedance matching present on both sides of the transformer (i.e. $R_s$ reflects to the source side as $R_s$ to ground, and $R_1$ reflects to the secondary side as the driving impedance for the non-inverting input terminating impedance, $R_1$).

Substituting with $R_1 = n^2 R_s$, and adding each noise voltage term squared divided by the output terminating impedance, $R_o$, will yield the total output noise power.
The input noise power may be derived as the power delivered to the source matching resistor from the source resistor noise voltage. This is:

\[ N_o = \left[ \frac{KTR_s}{2} \right]^2 + KTn^2R_s (\frac{A_y^2}{2} + \frac{n^2R_s}{2}) \left( \frac{A_y}{2} \right)^2 \]

The input noise power may be derived as the power delivered to the source matching resistor from the source resistor noise voltage. This is:

\[ N_o \rightarrow \frac{[\frac{1}{2} \sqrt{4KTR_s}]^2}{R_o} = KT \]

Pulling an \( \left( \frac{nA_v}{2} \right)^2 R_s \) out of the \( N_o \) expression, the ratio of input to output noise power may be rewritten as:

\[ \frac{N_o}{N_i} = \frac{(nA_v)^2 R_s}{4R_o} \frac{KT + KT + i_n^2 n^2 + \frac{e_m^2}{n^2R_s}}{KT} \]

Combining the expressions for noise power ratios and the inverse of the power gain through the channel, developed above, yields:

\[ \frac{S_i}{S_o} \frac{N_o}{N_i} = \left( 2 + \frac{\frac{n^2R_s}{4} + \frac{e_m^2}{n^2R_s}}{KT} \right) \]

Multiplying the fraction through, top and bottom, by \( R_s \) and going back to the log form for noise figure yields:

\[ NF = 10 \log \left( 2 + \frac{\frac{n^2R_s}{4} + \frac{e_m^2}{n^2R_s}}{KT} \right) \]

Looking at the component parts of this expression, the “2” in the log argument arises from our terminating with a discrete (noisy) matching resistor, \( R_s \). This increases the minimum achievable noise figure from 0dB to 10 • log(2) = 3dB.

The \( \left( \frac{n^2R_s}{4} + \frac{e_m^2}{n^2R_s} \right) \) part of the fraction represents the 2 noise voltages (the total equivalent input noise voltage and the voltage generated by the noise current through the source impedance) at the input of the amplifier reflected to the transformer input and added as powers across \( R_s \). The KT term in the denominator is simply the noise power available from the source at the input to the network. From this, as the turns ratio increases, the contribution of the noise current increases while that due to the noise voltage decreases. As reported in Reference 1, the minimum value will occur when these two terms are equal.

Solving for the optimum turns ratio to minimize the noise figure:

\[ n_{opt} = \sqrt{\frac{e_m}{i_n R_s}} \]

Substituting this in Equation 2 yields a minimum noise figure:

\[ NF_{min} = 10 \log \left( 2 + \frac{\frac{e_m}{R_s}}{KT} \right) \]

Recognizing that transformer turns ratios are actually only available in integer steps, the optimum turns ratio is somewhat academic. However, for a given \( n \), it can be recognized that anything that will reduce \( i_n \) or \( e_m \) will improve the noise figure.

Little can be done to reduce the noise current at the amplifier’s non-inverting input. The equivalent input noise voltage can, however, be reduced as the amplifier is operated at higher gains. The results in the appendix show that equivalent input noise terms due to the inverting noise current and resistor noises are reduced as the gain increases. However, once these noise terms have been reduced below the intrinsic non-inverting input noise voltage, further improvements through increased gain are minimal.

**Design Procedure and Test Results**

To illustrate the design procedure and the resulting performance using this input transformer coupling, two possible designs using the CLC400 and CLC401 will be developed. The designs will proceed with the assumption that the maximum gain consistent with broad bandwidth and good 3rd order intermod intercept is desired. Enough information is presented to allow a design to proceed from a targeted gain as well.

The CLC400 is a broadband DC coupled monolithic amplifier intended for relatively low gain operation. Typical specifications show a 200MHz bandwidth (−3dB) at a gain of +2. Both parts pull a nominal no load current of 15mA when operated from their recommended ±5 volt power supplies. For the current feedback topology, a low gain part corresponds to a part that has been optimized for a lower value of feedback resistor as opposed to a high gain part such as the CLC401. Hence, the nominal \( R_f \) at a gain of +2 for the CLC400 is shown on the data sheet as 250 ohms, while the CLC401 is optimized to use a 1.5k feedback at a gain of +20. Most of the requisite information for the design can be found in Comlinear Application Notes OA-12 (Noise Analysis) and OA-13 (Current Feedback Loop Gain Analysis).

Non-inverting input intrinsic noise voltage \( e_m = 2.5nV/\sqrt{Hz} \)

Inverting input noise current \( i_n = 14pA/\sqrt{Hz} \)
Non-inverting input noise current \( i_{n} = 3.2 \text{pA/} \sqrt{\text{Hz}} \)

Inverting input impedance \( Z_{i} = 50 \Omega \)

Nominal feedback transimpedance \( Z_{f} = 3500 \Omega \)
for maximally flat frequency response

Using these numbers, and Equation F in the appendix, a maximum amplifier gain for reduced equivalent input noise voltage may be derived as (this assumes an \( \frac{\omega}{c} \) of 1/9) \( G = 4.3 \)

Rounding this off to a gain of +4 yields a feedback resistor value of:

\[ R_{f} = Z_{f} - GZ_{i} = 150 \Omega \quad \text{(Eq. D in Appendix)} \]

Note that taking the gain too high will eventually yield very low \( R_{f} \) values from this equation. For very low values of \( R_{f} \), a significant degradation in both bandwidth and 3rd order intercept will be observed due to the added output stage loading presented by the feedback network. Generally, \( R_{f} + R_{g} = 2000 \) should be taken as a lower limit to \( R_{f} \).

Computing the equivalent input noise voltage for \( G = 4 \) using Eq. E of the appendix yields:

\[ e_{n} = \sqrt{(2.5 \text{nV})^2 + (2.67 \text{nV})^2} = 2.67 \text{nV/} \sqrt{\text{Hz}} \]

As hoped, this total equivalent input noise voltage is nearly equal to the intrinsic noise voltage listed above. From these results, and assuming a 500 \( \Omega \) source impedance, an optimum transformer turns ratio would be:

\[ n_{opt} = \sqrt{\frac{\theta_{opt}}{R_{S}}} = \sqrt{\frac{2.67 \text{nV}}{3.2 \text{pA} (25 \Omega)}} = 5.78 \]

This yields a best case noise figure equal to

\[ N_{F_{min}} = 10 \log \left( 2 + \frac{2.67 \text{nV} (3.2 \text{pA})}{4 \times 21} \right) = 6.2 \text{dB} \]

It is, however, difficult to maintain broadband performance through the transformer with a turns ratio this high. For test, a 1:4 turns ratio transformer from Mini-Circuits was selected as a reasonable compromise between best noise figure and broadband performance (part #T16-6T).

The resulting test circuit for the CLC400 is shown in Figure 3.

Using this test circuit, the anticipated performance can be calculated to be:

Overall Gain \( A_{v} = 4 \cdot 4 \cdot \frac{1}{2} = +8 \) (18dB)

Noise Figure (from Eq. 2)

\[ N_{F} = 10 \log \left( 2 + \frac{(4 (3.2 \text{pA}) 25 \Omega)^2 + (2.67 \text{nV})^2}{(4 \times 21) (50 \Omega)} \right) = 6.8 \text{dB} \]

In test, the first step was to tune the input impedance matching to provide a good 500 \( \Omega \) match over the frequency range of interest, after which the transfer function \( (S_{21}) \) was measured. These results are shown in Figure 4.
The measured noise figure shows excellent agreement with the predicted value, while the 3rd order intercept parallels the CLC400 data sheet plots. Note that the data sheets typically show intercept defined for a power level at the output pin as opposed to the 6dB lower value if defined at the matched load. Adding 6dB to the results shown above gives us back to the data sheet plots. This indicates that the intercept has not been degraded by the transformer input coupling.

Note that the noise figure for just the CLC400, configured as shown in Figure 3 without the transformer, may be derived by simply letting n = 1 in the noise figure equation (Equation 2). Doing this yields a noise figure of 15.8dB for the CLC400 by itself (assuming only a 50 ohm non-inverting input impedance matching resistor). Hence, the transformer not only provides us with more gain but with greatly improved noise figure.

In summary, this circuit shows a 50 ohm in/50 ohm out, 18dB gain block with very flat frequency response from 60kHz to 30MHz offering an approximate 7dB noise figure with a 3rd order intercept greater than 33dBm over that frequency range, while dissipating only 150mW quiescent power!

Design and Test Results for the CLC401

The CLC401 is a monolithic, DC coupled, wideband current feedback amplifier optimized for higher closed loop gains. Typical specifications show a 150MHz – 3dB bandwidth at a gain of +20 using a 1.5k feedback resistor while drawing only 15mA no load current from the specified ±5 volt supplies. Getting the requisite design information from Application Notes OA-12 and OA-13,

Non-inverting input intrinsic noise voltage \(e_n = 2.4nV/\sqrt{Hz}\)

Inverting input noise current \(i_i = 17pA/\sqrt{Hz}\)

Non-inverting input noise current \(i_n = 2.8pA/\sqrt{Hz}\)

Inverting input impedance \(Z_i \approx 50\Omega\)

Nominal feedback transimpedance \(Z_f = 2.5k\Omega\) for maximally flat frequency response

Using these numbers, and Eq. F of the Appendix, yields a maximum amplifier gain for minimal equivalent input noise voltage of (assuming \(\propto 1/9\)) \(G = 32.5\)

Building up the circuit at this gain and using the same transformer as for the CLC400 test circuit resulted in a 3dB response peaking at the higher frequency limits. This seemed to arise from a gain dependent non-inverting input impedance resonating with the transformer. Reducing the amplifier gain ameliorated this effect. Since the amplifier gain was being determined somewhat arbitrarily to reduce the noise figure, backing away from this gain to improve frequency response seemed reasonable. For test, an amplifier gain of \(G = +25\) was selected. Using Eq. E of the appendix shows an equivalent input noise voltage with a gain of +25 given by:

\[
e_n = \sqrt{(2.4nV)^2 + (17pA(50\Omega))^2 + 16E-21(50) = 2.70 nV/\sqrt{Hz}}
\]

With this result, an optimum turns ratio for the transformer and a theoretical best noise figure may be calculated to be:

\[
n_{opt} = \frac{2.70nV}{2.8pA(25\Omega)} = 6.2
\]

And

\[
NF_{min} = 10 \log \left( \frac{2.70nV(2.8pA)}{4E-21} \right) = 5.9dB
\]

Again, the high transformer turns ratio required for optimum noise figure would result in an unnecessarily limited bandwidth. Backing off to a 1:4 turns ratio transformer yielded the test circuit shown in Figure 6.

FIGURE 7 shows these results:

**Figure 7**

Note that for this test, the amplifier's gain setting resistor has been AC coupled with a 1\(\mu\)F capacitor. This is intended to reduce the DC gain for the amplifier's input offset voltage to 1, holding the output DC as close to 0 as possible. The capacitor value was chosen to yield a transfer function pole well below the transformer low frequency cutoff. The feedback resistor value is set using Equation D of the Appendix. The anticipated midband gain and noise figure performance can be calculated to be:

Overall Gain \(A_c = 4 \times 25 \times 1/2 = +50 \) (34dB)

Noise Figure (from Eq. 2)

\[
NF = 10 \log \left( \frac{2.70nV}{4(2.8pA)(25\Omega)} \right)^2 = 6.7dB
\]

As with the CLC400, the test sequence was to tune the input matching impedance network to yield a good 50ohm match over as wide a frequency range as possible. After this, the input to output transfer function was measured (\(S_{21}\)). Figure 7 shows these results:
This circuit doesn’t do quite as well in holding up the input impedance to higher frequencies but it does provide a reasonably flat frequency response from 70kHz to 50MHz (passband with \( < \pm 0.5\text{dB} \) ripple).

A measure of the noise performance was obtained using an HP3585 spectrum analyzer along with a CLC100 low noise wideband amplifier as a preamp to the analyzer input. Although accurate noise figure measurements are difficult to achieve in this fashion, this approach indicated noise figures between 7 and 8dB. Figure 8 tabulates the measured 3rd order intercept results and this estimated noise figure.

Comparisons and Conclusions

Clearly, the transformer coupling offers the potential for some real improvement in noise figures for the amplifiers considered here. Having given up the DC coupling in the process, however, we are now looking to compare these parts to the more classical AC coupled IF amplifiers.

Those parts generally use a Class A output stage as opposed to the Class AB structure used in most of Comlinear’s amplifier products. This, along with the high loop gain at lower frequencies, allows exceptional distortion performance to be achieved at a fraction of the quiescent power dissipation vs. the more classical Class A output. This advantage narrows as we move to frequencies over 100MHz with the op amp’s loop gain dropping below unity at these higher frequencies.

 Generally, for the lower frequency applications, the circuits described here, or similar circuits using different Comlinear amplifiers can offer considerable advantages in the areas of power dissipation, size, and cost.

The transformer coupling offers additional flexibility through potential signal inversion, by reversing the dot convention, output DC shifting, by inserting a DC voltage in place of the ground on the secondary, and potential narrowband filtering. If higher output power levels are desired, this same approach could be used with one of Comlinear’s hybrid op amps offering higher supply voltages and greater output power capability. The CLC232, for low gains, and the CLC207 for higher gains, are particularly low harmonic distortion parts that would also benefit, from a noise figure standpoint, from transformer coupling.

This approach to noise figure improvement is applicable to any op amp with an optimum source resistance greater than the actual source resistance. With the total equivalent input noise voltage at the non-inverting input decreasing as the closed loop gain is increased (as shown in the appendix), it is advantageous to operate the op amps at high gains. The current feedback topology, pioneered by Comlinear, is particularly suitable for wideband, high gain applications.

As described in Application Notes 300-1 and OA-13, the current feedback op amp topology largely eliminates the gain-bandwidth performance limitations plaguing earlier voltage feedback designs. Therefore, running the amplifiers to higher gains, in an effort to drive down the non-inverting input voltage noise, will not sacrifice broadband performance as it would using a voltage feedback part.

Appendix:

Computing the equivalent input noise voltage, the gain, and feedback resistor values for noise figure reduction with current feedback op amps.
The equations for determining the equivalent input noise voltage for use in the noise figure calculations will be developed. Since the external resistors around the amplifier, $R_i$ and $R_f$, play a large role in setting that noise, the amplifiers transfer function, which is also determined by these resistors, will be given and used to set the gain.

Figure A shows the necessary information to develop both the transfer function from $V_i$ to $V_o$ and the equivalent input noise voltage expression. As described in Reference 1, a current feedback amplifier uses a unity gain buffer from the $+$ input to the inverting node, $X_1$, with the inverting node current ($i_{err}$) acting as the feedback signal sensed and passed on to the output through a transimpedance gain, $Z_t$.

![Figure A](image)

Where:
- $K$—Boltzmann's constant
  - $1.38 \times 10^{-23} \text{ J/K}$
- $T$—degrees Kelvin
  - $290^\circ \text{K}$ used here

The goal here is to develop an equivalent non-inverting input noise voltage source to place at the non-inverting input for noise figure calculations. Normally, a noise generator for the non-inverting termination resistor would be included in this analysis. In the context of using an input transformer coupling, however, this resistor will be set by impedance matching concerns removing it as a variable for equivalent input noise voltage reduction. The effect of this resistor's noise is included in the development for noise figure. The 3 noise sources on the inverting side of the circuit must be reflected to the non-inverting side and combined with the intrinsic noise voltage, $e_{ni}$, already present in the model. Neglecting $i_{err}$, which is left separate for later use in the noise figure equations, each noise voltage or current will develop an output voltage noise. With the non-inverting signal gain defined to be $G = (1 + R_f/R_g)$, the separate output noise voltages are:

\[ e_{ni} \rightarrow \text{intrinsic non-inverting input noise voltage} \]
\[ i_{err} \rightarrow \text{inverting input current} \]
\[ \text{combined resistor noise terms} \rightarrow \sqrt{4kTR_i/G} \]

Combining terms as the root sum of squared elements, and reflecting this to the non-inverting input yields

\[ \text{equivalent input noise voltage} \rightarrow \sqrt{(e_{ni})^2 + \left(\frac{i_{err}}{G}\right)^2 + \frac{4kTR_i}{G}} \]  

Eq. C

As is apparent from this expression, both the gain and the resistor values can be used to reduce the input noise voltage. Increasing the gain and/or reducing the resistor values will both decrease the apparent input noise voltage. This effort is bounded by the intrinsic input noise voltage, $e_{ni}$.

Setting the gain and the resistor values needs to be done in the context of maintaining adequate phase margin for the closed loop amplifier response. Analyzing the circuit of Figure A for the $V_o/V_i$ transfer function yields (see Application Note OA-13 for a more complete development):

\[ V_o = \frac{V_i}{1 + \frac{1+R_f/R_g}{R_i + Z_f(1+R_f/R_g)}} \]

\[ = \frac{G}{1 + \frac{R_i + GZ_f}{Z_f}} \]

\[ \text{where: } Z_f \rightarrow \text{Forward transimpedance gain of the amplifier (frequency dependent)} \]
\[ Z_i \rightarrow \text{Inverting input impedance (Considered noiseless and real)} \]

The inverting node current is the feedback signal with an output voltage to inverting current transfer gain given by $Z_i = R_i + Z_fG$

Every current feedback amplifier has an internal forward transimpedance gain function ($Z_f$) optimized for a certain value of $Z_i$. Typically, this optimization yields a $60^\circ$ phase margin at the gain and feedback resistor value specified on the data sheet for guaranteed performance specs. To a first approximation, this $Z_i$ can be held constant (maintaining maximum closed loop bandwidth with no peaking) as the desired closed loop signal gain is changed from the nominal design point. This is done by adjusting $R_f$ vs gain. Solving for this from the above expression for $Z_i$ yields:

\[ R_f = Z_i - Z_fG \]

Eq. D
If this expression for $R_i$ is placed into the equivalent input noise expression developed above, Eq. C, we get:

$$e_{in} = \sqrt{(e_{in})^2 + i_1^2 \left( \frac{Z_i}{G} \cdot Z_j \right)^2 + 4KT \left( \frac{Z_i}{G} \cdot Z_j \right)} \quad \text{Eq. E}$$

The only variable left at this point is the desired closed loop gain. The absolute resistor values have been removed with the assumption that a maximally flat frequency response is desired as the closed loop gain is changed. Again we see that increasing the gain will decrease the equivalent input noise voltage. This approach is decreasingly effective as those terms involving $G$ become less than the non-inverting input noise voltage $e_{ni}$. If we target a desired ratio of the two squared terms involving $G$ to the intrinsic non-inverting input noise voltage squared, we can develop a targeted maximum gain beyond which minimal noise reduction is achieved through further gain increases. If we call that ratio of the noise powers $\propto$ we can solve for:

$$\left( \frac{Z_i}{G} \cdot Z_j \right) = \frac{2KT}{i_1^2} \left[ \sqrt{1 + \propto \left( \frac{e_{ni} \cdot i_1}{2KT} \right)^2} - 1 \right] \quad \text{Eq. F}$$

From this expression, and a knowledge of $Z_i$ and $Z_j$, a maximum desired gain may be derived. This yields a somewhat arbitrary upper limit on amplifier gain in that we are only trying to increase the gain until negligible improvements in the noise figure are seen. The amplifier can, of course, be operated at lower gains, with an increase in noise, or at higher gains, with little noise improvement but an eventual bandwidth limitation. If we set $\propto$ to be $1/9$ (saying that the reflected equivalent noise power terms at the non-inverting input are $1/9$ the intrinsic input noise power due to the non-inverting input noise voltage) those terms increase the equivalent input noise voltage by only 5%. This will be the initial targeted design criteria used in the example developments.

See Application Note OA-13 for a complete development of adjusting $R_i$ to hold a constant loop gain, and hence bandwidth, as the desired signal gain is changed.
APPLICATION NOTE OA-15

Frequent Faux Pas in Applying Wideband Current Feedback Amplifiers

Michael Steffes
As op amp operating speeds have moved to ever higher frequencies, a whole new set of design concerns have come into play for linear op amp applications. With the development of the current feedback topology, design concerns unique to that topology must also be considered if optimal performance is to be achieved from devices offering over 200MHz – 3dB bandwidths. This discussion will review some of the considerations common to all wideband linear op amp applications as well as topics unique to the current feedback topology pioneered by Comlinear Corporation. These design guidelines are intended to help the designer get the full potential out of Comlinear’s high performance, current feedback, operational amplifiers.

Since there are quite disparate areas to consider here, the approximate order of discussion will follow a perceived frequency of occurrence ranking. Those considered first seem to impact every designer, with more particular concerns dealt with later.

1. Parasitic capacitance effects and what to do about ground and power planes in a PC board layout.

The sensitivity of the Comlinear amplifiers to parasitic capacitance arises solely from their wide bandwidth characteristics and not from the current feedback aspect of their design. With parts showing a loop gain that does not drop to unity until the 100MHz region, a few picofarad capacitance to ground in the loop can have a profound effect on the phase margin at the unity gain crossover frequency. Figure 1 shows a typical non-inverting gain op amp, including the internal structure for the current feedback topology (note 1), along with the two most critical external parasitic capacitances.

![Figure 1: Non-inverting gain with internal current feedback topology](image)

Note 1: See application note AN, AN-300, or OA-13 for a development of the current feedback transfer function.

Parasitic, or loading, capacitance directly on the output is particularly effective at transforming amplifiers into oscillators. Closed loop stability for any negative feedback amplifier is determined by the open loop phase margin. In tracing the signal around the loop it is always desirable to have significantly less than 180 degrees phase shift around the loop at the unity gain crossover frequency. Adding a capacitor directly on the output will cause additional signal phase shift due to the additionally pole introduced by the open loop output impedance, \( R_o \), driving the output pin capacitance, \( C_{po} \). Even small capacitances and low \( R_o \)'s can cause significant phase shifts with unity gain crossovers in the 100MHz region (a typical unity gain crossover frequency for Comlinear amplifiers).

Several design and test guidelines can be suggested to keep this sensitivity to \( C_{po} \) under control.

a. Always clear ground and power planes away from the output pin net. This includes opening up a little wider than standard clearance to ground and power inner planes to any through hole or trace carrying the output signal.

b. Never probe directly with a high impedance probe or a DVM on the output pin (passive divider probes are okay). If probing, always probe through a series resistor \( \geq 1000\Omega \) since this will decouple the effect of the probe capacitance from the output pin. This also helps for adding PC board test points. If needed, connect the test points through a series resistor located as close as possible to the device pin being brought out.

c. If a capacitive load must be driven, such as flash ADC's, most of the Comlinear amplifier data sheets include a plot of a recommended series resistor to put at the output prior to the load capacitance. Adding a resistor prior to the load (or parasitic) capacitance, changes the load's effect from a pole to a pole-zero pair. This causes a phase dip in the loop phase response that has recovered prior to unity gain crossover.

Figure 2 shows the effect of a capacitive load on the small signal frequency response of the CLC205, a hybrid current feedback op amp intended for higher gains. The plot shows the SPICE simulated gain, in dB, vs. linear frequency under several loading conditions. Similar plots may be generated using the small signal macromodels of Application Note OA-09. Initially, a 2000\( \Omega \) load is driven, then just a 20pF load, and finally, the 20pF load with a series 30\( \Omega \) resistor (\( R_o \) in Figure 2a). Clearly, getting into a series resistor prior to the capacitive load can dramatically improve the frequency response flatness, and hence pulse response capabilities for the amplifier simulated here. Recall that this approach is applicable for both current and voltage feedback amplifiers.

Generally, it is suggested to get the output voltage through a resistor as soon as possible before running it over any significant length of trace or cable. If a matched impedance load is to be driven, source match right at the output pin with a discrete resistor equal to the transmission line's characteristic impedance, and terminate the line similarly. Although short trace runs do not need to be impedance matched, using just the series resistor will isolate the trace capacitance when
no terminating resistor is used.

Figure 2a: Simulation circuit for capacitive loading test

Figure 2b: Frequency response for various loadings

Parasitic capacitance on the inverting node is a considerably more complex, but not nearly as troublesome, phenomena. Capacitance on this input affects both the non-inverting signal gain, by appearing in shunt with the gain setting resistor, and the loop gain phase margin in a 2nd order sense. Two types of pulse response characteristics can be observed due to this parasitic. If the dominant effect is simply shunting $R_g$ in the ideal gain expression, neglecting loop gain effects for now, a single overshoot with a decay will be observed. If this capacitance is large enough to effect the phase margin, considerable ringing in the pulse response will also be observed.

Again, minimize ground and power planes around the inverting node net. The single overshoot and decay will most often be observed when a current feedback part intended for higher gains, and hence designed to use a relatively high feedback resistor value, is used at low non-inverting gains. The relatively high $R_g$ required to get a low non-inverting gain will bring the impact of whatever parasitic is present down in frequency into the passband of the amplifier. The solution here, beyond simply limiting $C_{pi}$, is to run inverting mode if possible, or switch to a part intended for lower gain operation, and hence designed to use lower resistor values. Given a fixed $C_{pi}$, operating with lower $R_t$ and $R_g$ will move the zero frequency out beyond the amplifier passband. Application Note OA-14 discusses in more detail the gain range considerations for current feedback amplifiers.

Figure 3 shows a test circuit and simulation results demonstrating the effect of inverting node capacitance for the CLC205 operated at relatively low non-inverting gain.

The effect of increasing $C_{pi}$ from .5pF to 5pF in the circuit of Figure 3a can be seen as a considerable peaking in the frequency response of Figure 3b. This is not, in this case, a loss of phase margin peaking, but simply a zero coming into the non-inverting transfer function due to $C_{pi}$ shunting $R_p$. This zero frequency is at $(C_{pi} \cdot (R_g/R_t) / (2 \cdot \pi))$ Hz. Note in the pulse response of Figure 3c that $C_{pi}$ causes a single overshoot with negligible ringing.
If ringing is observed in the pulse response, this is more likely due to capacitance on the output pin. However, larger parasitic capacitances on the inverting node (>10pF) can also cause loop gain phase margin problems, particularly for parts intended for high gains. Again, the discussion about avoiding parasitic capacitances on the output pin applies equally well here. Figure 4 shows the difference in pulse response behavior between $C_{po}$ and $C_{pi}$ effects. The upper trace, which was plotted with a 1V offset for clarity, shows the ringing pulse response for the most peaked response of Figure 2b. This is typical of output pin capacitance effects. The lower trace is a repeat of the $C_{pi} = 5pF$ pulse response of Figure 3c.

Parasitic capacitance to an AC ground on the non-inverting input, including the capacitance of the high impedance non-inverting input itself, will generally only introduce an additional response pole, depending on the source impedance driving the input capacitance. For low source impedances, this pole comes in well beyond the passband of the amplifier. However, when the parasitic capacitance on the non-inverting and inverting nodes are approximately equal, intentionally adding non-inverting source impedance equal to $R_{ni} / (R_{pi} + R_{ni})$ can be very effective at cancelling the response zero coming in through $C_{pi}$ shunting $R_g$.

Figure 5 shows this approach with the $C_{pi} = 5pf$ case considered earlier in Figure 3. Note that we have intentionally matched the capacitance at the non-inverting input and added $R_{ni} = 300$ to bring the frequency response back to flatness. The signal gain is not changed by the addition of $R_{ni}$. This approach simply cancels the zero apparent in the upper trace of Figure 5b, significantly decreasing the pulse overshoot as shown in Figure 5c.

Although it is critical to remove ground plane from the signal input and output nodes, a good, low inductance, ground return path must be provided for the AC load current. This is typically provided by putting small-valued ceramic capacitors directly on the power supplies, connected to a good adjacent ground plane. These conflicting goals of good power supply grounding with no parasitic capacitance on the I/O pins can be achieved by opening a window around the part for the ground and power planes with the high frequency decoupling capacitors connecting into this ground plane. The layout drawing of the 730013 evaluation board (in the product accessories section of the catalog), shows a good high frequency layout for the 8-pin DIP monolithic amplifier products offered by Comlinear.

Figure 6 shows the same amplifier as Figure 1 with the suggestions for handling parasitic capacitances incorporated.
Figure 6: Non-inverting amplifier featuring several suggested protections from parasitic capacitance effects

The circuit of Figure 6 includes every fix for the possible problems arising from parasitic capacitance discussed thus far. Very rarely would all of these be required for the same application. If test points are to be brought out, always come out through at least 100Ω resistors with the body of those resistors as close as possible to the amplifier pins. Probing at these test points can still radically alter the signal path frequency response. The amplifier should, however, remain stable with at least 100Ω isolating resistors. If inverting node parasitic capacitance seems to be a problem, $R_p$ can be very effective at cancelling it out (except when $C_{pi}$ is so large as to cause phase margin problems). If a parasitic or load capacitance must be driven, $R_s$ may be used very effectively to improve the frequency response flatness. And, always get the high frequency capacitors on the power supplies as close to the part as possible into a good ground plane.

2. The importance of the feedback resistor
The feedback resistor value becomes of paramount importance in the current feedback topology used by most of the Comlinear amplifiers. As discussed in detail in Application Note OA-14, the feedback resistor is the single most important element in setting the overall frequency response for the current feedback amplifier topology. Briefly, since we are looking for a feedback current from the output voltage to the inverting input, the feedback impedance plays the dominant role in determining what this will be. This, in turn, will determine the amplifier’s loop gain and phase margin. Achieving adequate phase margin is critical to the success of any operational amplifier application.

Every current feedback amplifier is optimized for a particular value of feedback resistor. This value is typically noted at the heading of the specifications listing. Always select a value near this as the starting point for any design. Lower values may be used at the risk of lower phase margin and greater frequency response peaking. Higher values may be used at the expense of lower amplifier bandwidth. In fact, increasing the feedback resistor value is a very effective means of overcompensating the amplifier. Unlike voltage feedback amplifiers, a unity gain follower application requires the recommended feedback resistor to be in place from the output to the inverting input. Although having no influence on the low frequency signal gain in the unity follower application, the feedback element is still needed to determine the loop gain for the current feedback topology.

Using reactive elements in the feedback path, either intentionally or unintentionally, can play havoc with the loop gain phase margin. Generally, this should be avoided unless done with extreme care. The small signal macromodels in Application Note OA-9 are very useful for predicting what will happen with different feedback configurations. Using direct capacitive feedback, to implement an integrator, will generally cause oscillations with a current feedback amplifier. Integrators can be implemented, however, using the alternative topologies shown in Application Note OA-7. Also, the CLC420, a wideband voltage feedback op amp, can be used to implement classical integrator topologies.

Returning to the feedback resistor itself, never use a wirewound type for this, or any other, resistor in a broadband application. Also, trying to compensate the amplifier by using shunt capacitance across $R_s$ will typically yield oscillations with the current feedback topology. It is much more fruitful to compensate by increasing the value of the feedback resistor, although a pot in the feedback path is not recommended.

3. Non-inverting source impedance considerations
The impedance seen looking out of the non-inverting input can play a strong role in determining an amplifier’s overall performance. For very broadband applications, significant resistive source impedance, in conjunction with the part’s input capacitance, can become the bandlimiting point in the system. This is normally not a problem for 50Ω terminations driven from a 50Ω source.

When running the amplifier in inverting mode, the non-inverting input would typically be grounded, either directly, or through an approximately 25Ω resistor. No attempt at source impedance matching on the two inputs for bias current cancellation should be made since the two bias currents for a current feedback amplifier are totally unrelated in both magnitude and polarity. Hence, unlike a voltage feedback op amp, there is no meaning to an offset current specification.

Generally, taking the non-inverting input to ground through a 25Ω resistor (for inverting amplifier applications) will eliminate any oscillations that might be seen due to negative input impedance effects at very high frequencies for the non-inverting input. It is oftentimes sufficient to simply ground the non-inverting input. But a careful check for low level oscillations above 500MHz should be made, particularly for the faster amplifiers, if direct grounding is desired. If oscillations are observed, going to a 25Ω, or higher, resistor to ground will kill this self oscillation in the non-inverting input transistors.

When it is desired to AC couple the non-inverting input signal, as shown in Figure 7, particular attention must be paid to the effect the terminating resistor has on the DC operating point of the amplifier. Oftentimes, in an effort to achieve very low pole frequencies for the AC coupling (without an inordinately large coupling capacitor, $C_o$), $R_t$ is made very large or, in some cases, not included.
The common mode input simply follows the non-inverting even for differential these specifications as a required voltage headroom for non-standard supply voltages. When operating properly, the inverting node voltage will be the required voltage headroom to the supplies on the inverting input and output pins respectively. Recasting inverting input bias current. Wideband amplifiers with a purely bipolar construction, as Comlinear’s amplifiers typically are, have an input bias current ranging into the 10’s of μA’s. It is critical, therefore, to consider the effect a large \( R_I \) has on the input offset voltage (as shown in Figure 7). It is very easy, with large \( R_I \), for this bias current requirement to have driven the input and output into saturation precluding proper high frequency operation. The effect of high \( R_I \) on the non-inverting noise current gain should also be considered. This noise current will add as an input noise voltage term dependent on the frequency dependent source impedance looking back out the non-inverting input.

**4. Input and output voltage range considerations**

The common mode input voltage range specification (CMIR) shown in the Comlinear data sheets indicates how near the specified supply voltages the non-inverting input voltage may be for proper operation. When operating properly, the inverting node voltage simply follows the non-inverting even for differential amp applications. For current feedback, this is due to the unity gain buffer from \( V^+ \) to \( V^- \), while for voltage feedback, this is due the feedback loop.

Since all of the amplifiers are specified with balanced bipolar supply voltages, the CMIR and output voltage ranges are given as an allowed bipolar swing around ground. Both specifications are, however, indicating the required voltage headroom to the supplies on the non-inverting input and output pins respectively. Recasting these specifications as a required voltage headroom would allow input and output voltage ranges to be set for non-standard supply voltages.

In almost all cases, the maximum output voltage swing will be the limiting factor. Only at very low non-inverting gains, or for single amplifier differential operation, will the CMIR limit operation. The crossover non-inverting gain where the limiting point will change from input to output can be found by dividing the output voltage range by the input voltage range.

Operation that can cause the amplifier to exceed its output voltage range should be handled with special caution. Except for devices including an output limiting or clamping function (CLC500, CLC501, CLC502), exceeding the output voltage range will result in saturation internal to the amplifier. In all cases, this will result in very slow recovery time from overdrive. Since the error signal, for current feedback, is a current back to the inverting input, saturating the output voltage so that it no longer fully supplies the current being set up in the gain setting resistor will cause a current to build up in the inverting input. This is analogous to a voltage developing across the inputs of a voltage feedback amplifier when overdriven. This inverting input current can also limit recovery time from saturation effects internal to the amplifier.

All of the monolithic amplifiers from Comlinear can handle this saturation without damage. Extreme overdrives at the inputs can, however, exceed the current handling capability of the inverting node at which point a voltage will start to build across the inputs. This can, if large enough, break down some internal junctions leading to an increase in noise and possibly a shift in the DC characteristics of the amplifier.

Unless specifically indicated as overdrive protected (CLC205, CLC206, CLC207, CLC560, CLC561), special care should be taken not to drive any of the hybrid amplifiers into output saturation. Intended for the widest band, high power operation, these parts have enough internal drive capability to potentially damage themselves under a saturated output condition. Although not noted in the data sheets, the CLC231 and CLC232 low gain hybrid amplifiers can also be output stage saturated without damage. Even with an output saturable capability, all of the hybrid amplifiers need a careful analysis of junction temperatures to ensure that they do not exceed the rated maximum of 175°C.

From these considerations, it is not recommended that these unprotected hybrid amps be used as comparators – with the output intentionally forced from supply rail to supply rail. (The fast recovery clamping of the CLC501 does, however, offer an excellent opportunity for a very flexible high speed comparator function.) It is also not recommended to increase the value of the output stage collector resistors, for those parts bringing the output transistor collectors out separately, to act as a current limit since this will only saturate the output stage sooner. Generally, these resistors are intended only to de-couple high speed load current transients from the rest of the amplifier to enhance high speed settling times. It is possible, however, to use these resistors as an output short ckt current limit for those parts indicated as being overdrive protected. And finally, when using adjustable gain circuits, particularly with switching FETs, take care to keep the amplifiers out of an open loop situation during gain adjust.

For situations requiring a robust output overdrive capability, the clamping amplifiers are by far the best choice.

**5. Cascaded amplifier considerations**

High gain, cascaded amplifier applications require particular attention to a number of parasitic and operational effects. Figure 8 shows an example circuit of 3-CLC401’s configured for an overall gain of 1000 (60dB) that will be used to demonstrate the suggestions developed here.

Several opportunities exist to develop an oscillator with very high gain, wideband circuits. The most common
Figure 8: Wideband, high gain, cascaded amplifiers

is direct output to input parasitic coupling. The output signal path should be physically isolated and, if necessary, shielded from the input signal path. When the final output is driving a relatively heavy AC load, either capacitive or, in this case, resistive (100Ω), high frequency load currents through the supplies can couple back into early stages completing an oscillatory feedback loop. High frequency de-coupling directly on the supply pins of each stage are required at a minimum.

Interstage ferrite beads on the supply rails, as shown in Figure 8, can also be used to attenuate this feedback path. The power supply connections of Figure 8 bring in the supplies at the final gain stage with LC PI filter stages used as it connects into earlier amplifier stages. This provides increasing high frequency attenuation as we go to amplifier stages earlier on in the gain path. This is very desirable from both a PSRR standpoint and in breaking any feedback path through the power supplies from the output to input.

For close physically coupled amplifier stages, interstage matched impedances are probably not necessary. The two interstage 40Ω resistors of Figure 8 are intended to isolate the input capacitance of the next stage from the output of the previous stage as suggested earlier in the discussion of parasitic load capacitance effects.

One key concern in a very high gain path is the build-up of DC errors. The circuit of Figure 8 AC couples the gain setting resistors which reduces the DC gain to 1 for each amplifier stage. With only 1mV input offset voltage at the first stage, the final amplifier output, (prior to the 6dB matching loss), would be at 2V for this gain of 2000 if the 1μF capacitors had not been used in the gain setting networks. If DC coupling at high gains is desired, some sort of composite correction loop (as described in Application Note OA-07) should be considered.

As a general rule, the highest gain stage should be used as the first stage to limit the impact on the overall input noise of the noise contribution of succeeding stages. Here, the equivalent input noise of the 2nd two stages would be divided by the gain of +20 in the first stage in adding to overall equivalent input noise. The total equivalent input noise for the circuit of Figure 8 is 3nV/√Hz. See Application Notes OA-12 for a noise calculation discussion and OA-14 for reducing the input noise for AC coupled applications.

Figure 9 shows the measured broadband gain and phase response for the circuit of Figure 8. Note that the measured ~3dB bandwidth, extending from 3KHz to 200MHz, achieves an equivalent 200GHz Gain-Bandwidth product.

Figure 9: Measured Gain & Phase for high gain cascaded circuit
Wideband AGC Amplifier Doubles as a Differential Amplifier

Michael Steffes
The CLC520 is a very flexible DC-coupled Automatic Gain Control amplifier (AGC). Unique features include two closely-matched differential inputs, a wideband gain-control channel (100 MHz), and a ground-referenced DC-coupled output signal driven from a low output impedance amplifier. Figure 1 illustrates the internal block diagram and pin assignments of the CLC520.

Figure 1: CLC520 Internal block diagram

As shown in figure 1, two unity-gain closed-loop input buffers on pins 3 and 6 are used to force the two input voltages to appear across the external resistor, $R_p$. The differential voltage across $R_p$ generates a signal current which is amplified by a factor of 1.85 and fed into a two-quadrant multiplier stage. The gain-adjustment voltage on pin 2 determines how much of this signal current makes it through the multiplier stage, with the remainder of the signal current being shunted to ground. The multiplier’s output current then flows through the transimpedance amplifier formed by the external feedback resistor, $R_t$, and the internal amplifier. If the non-inverting input of this output amplifier, $V_{in}$, is tied to ground then a ground-referenced DC-coupled replica of the differential voltage across $R_p$ appears at the output of the op amp. The values of $R_t$ and $R_p$, along with the gain-adjust voltage, determine the gain. Refer to the CLC520 data sheet for a more complete operational and performance discussion.

In order to implement a fixed-gain differential amplifier, the CLC520 will rely on it’s very well-matched input buffers and it’s differential-to-single-ended voltage conversion. For the purposes of this discussion, the gain-control input will be held at a fixed level to yield the maximum gain given by 1.85-$R_t/R_p$. Thus, the differential signal gain depends only on the ratio of two external resistors and the internal current-mirror gain. Both $R_t$ and $R_p$ can be adjusted to yield a wide range of differential gains. As an example, the circuit of figure 2 is used to demonstrate the performance of the CLC520 in a fixed-gain differential amplifier configuration.

To demonstrate this application, the CLC520 is set up for a gain of 4.08V/V. The 50Ω impedance-matching resistor at the output effectively halves the differential gain to 2.04V/V (6.2dB) at the 50Ω load. Figure 3 shows the single-ended gain and phase response for both inputs on a linear frequency scale through 200MHz. Note the 180° phase offset for the inverting-signal gain, indicating signal inversion. The slightly quicker roll-off of the inverting-gain response is consistent from part to part. This broadband performance is maintained as the part is operated at higher gain settings. It is the close, broadband, gain match of the inputs that allows the CLC520 to provide this wideband differential amplifier with very good common-mode signal rejection.

Figure 2: CLC520 Fixed-gain differential amplifier configuration

One measure of a good differential amplifier is its ability to reject common-mode signals. The common approach in describing this rejection is as a Common Mode Rejection Ratio (CMRR). The definition of CMRR is structured to allow the common-mode input signal to be placed in series with one of the differential inputs, (divided by CMRR), as an equivalent error term. With the following definition of CMRR, an equivalent input error term is placed at one of the inputs as shown in figure 4.
Ad: Differential gain
Ac: Common-mode gain

\[
CMRR = \frac{Ad}{Ac}
\]

\[
CMRR = 20\log(Ad) - 20\log(Ac)
\]

Eq. 1

Figure 4: Input-referred common mode error model

\[
V^+, V^-: \text{pure differential signals} \\
V_c: \text{common mode signal element} \\
V_o = Ad(V^+ - V^-) \pm \frac{V_c}{CMRR} Ad \\
= Ad(V^+ - V^-) \pm \frac{V_c}{Ad / Ac} Ad \\
= Ad(V^+ - V^-) \pm V_cAc
\]

This definition of CMRR essentially input refers an output signal due to a common-mode input signal which effectively holds the common-mode gain constant as the differential gain is changed. In computing the actual input-to-output signal gain due to a common-mode input voltage, simply use Ac. Note, with Ac<<1, the logarithmic form of CMRR yields a large positive value. However, in computing the output common-mode signal, as shown in figure 4, a linear (Volts/Volts) gain must be used and the error must be considered bipolar.

To measure the CMRR as defined in figure 4, a measure of the pure differential gain must first be made. This measurement can be accomplished with the circuit of figure 5. This circuit uses a transformer with a center-tapped secondary to generate a pure differential input signal. The center tap also provides a DC path to ground supplying a DC-bias current to each of the inputs. It is necessary, in all cases, to carefully consider the source of these DC-bias currents. The transformer’s frequency response was normalized prior to the gain and phase response measurement. Although using this transformer effectively AC couples the differential gain, it is important to recognize that the CLC520 is a truly DC-coupled device.

The measured gain and phase for the circuit of figure 5 are shown in figure 6. In order to maintain compatibility with the common-mode gain measurement, this figure is represented with a logarithmic frequency sweep from 100kHz to 100MHz. This circuit offers an exceptional gain-flatness with only 0.5dB rolloff to 100MHz.

The common-mode gain is measured by replacing each of the 50Ω input resistors of figure 2 with 100Ω while connecting the two inputs together. Tying the inputs together forces the input signals to be exactly the same while the resistor replacement retains the 50Ω input-impedance match. In an actual application, connecting the two inputs together is impractical. In most cases the common-mode gain is not set by the amplifier, but by the mismatch of signal attenuations arising from each signal-source’s impedance into the single-ended input impedance of each of the differential amplifier’s inputs. A careful attention to the signal-source impedance match is necessary in order for the CMRR performance to be dominated by the amplifier and not by the deleterious effects of signal-source impedance mismatches. The common-mode gain measurement made here sidesteps those issues by simply tying the two inputs together. Figure 7 shows the CMRR using the measured differential gain, the measured common-mode gain and the logarithmic form of CMRR (Eq.1).

The upper limit of CMRR at low-frequencies (below 100kHz) is approximately 70dB. This limit is set by the differential-to-single-ended conversion that takes place internal to the CLC520. At higher frequencies, the
divergence in single-ended gains results in a 40dB rolloff of CMRR at 10MHz (shown in figure 3). The CLC520's two high-impedance inputs with its internal wideband differential-to-single ended conversion combine to form a very wideband, high CMRR, differential amplifier.

Once the parasitic capacitance to ground on pins 4 & 5 has been minimized, a frequency response similar to that shown in figure 3 can be achieved for each of the two inputs separately. It is possible to take advantage of a parasitic gain imbalance in order to bring the inverting gain, at higher frequencies, into a closer match with the non-inverting gain. A closer gain match over a wider frequency range will improve the CMRR at high frequencies.

Although the equivalent circuit of figure 1 shows an output that depends only on the current through Rg, any additional current driven in to or out of the buffers will also generate an output signal. Therefore, by adding an AC coupled path to ground on the output of the inverting buffer, its response can be matched to that of the non-inverting buffer. The circuit of figure 8 shows the original test circuit with the addition of this frequency-response-matching network (R_T and C_T).

The single-ended frequency responses shown in figure 3 show a lower bandwidth for the inverting gain path vs. the non-inverting. This bandwidth mis-match is consistent from part to part and is set by the internal gain path. The buffer bandwidths are considerably higher and do not play a role determining this response. The following analysis will show how to select the appropriate values for R_T and C_T such that the frequency response of the inverting gain path can be matched to that of the non-inverting gain path.

The single-ended frequency responses shown in figure 3 show a lower bandwidth for the inverting gain path vs. the non-inverting. This bandwidth mis-match is consistent from part to part and is set by the internal gain path. The buffer bandwidths are considerably higher and do not play a role determining this response. The following analysis will show how to select the appropriate values for R_T and C_T such that the frequency response of the inverting gain path can be matched to that of the non-inverting gain path.

\[
\omega^+ : \text{Non-inverting response pole} \\
\omega^- : \text{Inverting response pole}
\]

Non-inverting frequency response:

\[
A^+ = \frac{\omega^+}{s + \omega^+}
\]
Inverting frequency response:

\[ A^- = \text{Ad} \left( \frac{\omega^-}{s + \omega^-} \right) \]

Assuming \( \omega^- < \omega^+ \)

Compensate \( A^- \) to achieve the following

\[ A^+ = \text{Ad} \left( \frac{\omega^+}{s + \omega^+} \right) \]

\[ = \text{Ad} \left( \frac{\omega^-}{s + \omega^-} \right) \left( \frac{s + \omega^-}{s + \omega^+} \right) \left( \frac{\omega^+}{s + \omega^+} \right) \]

\[ = \text{Ad} \left( \frac{\omega^+}{s + \omega^+} \right) \]

The single-ended gain response of either input may be analyzed by grounding one input in order to determine the current generated at the output of the active buffer channel. Adding the \( R_T C_T \) series combination will then provide a means of canceling the internal inverting-path pole with a zero, and replacing it with a pole that matches that seen by the single-ended non-inverting gain path. Note, adding this network will not impact the non-inverting response as long as it is assumed the buffers have zero output-impedance. The following analysis provides a method for computing the required values of \( R_T \) and \( C_T \) given \( R_g \) and the initial single-ended frequency response of each input as shown in figure 3. Note: the input-to-output gain from the current produced in the compensation path is \( \frac{1}{2} \) that of the gain of the current produced through \( R_g \).

The output voltage due to an inverting input voltage is:

\[ V_o = - \left[ 1.85 (l_2) R_T + \frac{1}{2} (1.85) l_1 R_f \right] \left( \frac{\omega^-}{s + \omega^-} \right) \]

\[ l_1 = \frac{V^-}{R_T + \frac{1}{s C_T}} \]

and \( l_2 = \frac{V^-}{R_g} \). \( \omega^- = \text{single-pole response} \)

Solving this for the gain to the output:

\[ \frac{V_o}{V^-} = -1.85 \frac{R_f}{R_g} \left[ \frac{1}{s + R_f R_T} \right] \left( \frac{s + \frac{1}{R_T C_T}}{s + \frac{1}{R_T C_T}} \right) \left( \frac{\omega^-}{s + \omega^-} \right) \]

The non-inverting path has a gain of:

\[ \frac{V_o}{V^+} = 1.85 \frac{R_T \left( \frac{\omega^+}{s + \omega^+} \right)}{R_g \left( \frac{\omega^+}{s + \omega^+} \right)}, \omega^+ = \text{single-pole response} \]

Equating these two gains requires a cancelling of the \( \omega^- \) pole with the zero developed by the \( R_T C_T \) network while placing the \( R_T C_T \) pole at \( \omega^- \).

Solving for \( R_T \) and \( C_T \)

\[ R_T = \left( \frac{\frac{1}{2} R_g}{\frac{\omega^+}{\omega^+} - 1} \right), \quad C_T = \left( \frac{1}{R_T \omega^+} \right) \]

Estimating \( \omega^- \) and \( \omega^+ \) from the -1dB roll-off frequencies of figure 3 and using

\[ \omega^-_{-3dB} = 1.97 \quad \omega^-_{-1dB} \text{ for a 1-pole response roll-off} \]

\[ \omega^- = 2\pi(176\text{MHz}) \]

\[ \omega^+ = 2\pi(240\text{MHz}) \]

\( R_T \) and \( C_T \) therefore,

\[ R_T = \left( \frac{216}{240 - 1} \right) = 595 \Omega \]

\[ C_T = \left( \frac{1}{(595\Omega)2\pi(240\text{MHz})} \right) = 1.12 \text{pF} \]

Figures 9 & 10 show the resulting single-ended frequency responses and the CMRR achieved through this compensation. Comparing figure 9 to figure 3 shows a much closer match over frequency. A significant improvement in the high-frequency CMRR has been achieved with this simple approach. \( C_T \) should be tuned for best CMRR at these higher frequencies. Note: when using different values of \( R_f \) and \( R_g \), a remeasurement of the single-ended gains is required in order to provide the single-ended gain poles necessary for this compensation analysis.

II. Setting the Differential Gain

To use the CLC520 at a fixed gain, it is best (from a temperature stability standpoint) to operate at its maximum gain, determined by \( R_f \) and \( R_g \). The adjustable portion of the CLC520's gain is set by a two-transistor internal differential stage which compares the voltage seen on pin 2 to an internal reference voltage developed as a resistor divider from the positive supply to ground. With approximately 750Ω internally to ground on pin 2, the 400Ω external resistor shown on the circuits above will develop approximately 3.3 volts at pin 2, insuring the internal gain stage is fully switched to maximum gain.
Figure 9: Single-ended gains with inverting-path compensation

Figure 10: Improved CMRR with better response-match over frequency

Note that the signal gain is also dependent on an internal current-mirror gain from the current developed in Rg to the multiplier stage. This nominal 1.85 factor will show some part-to-part tolerance and a slight temperature dependence. A ±3% part-to-part tolerance in this current gain along with a +80ppm/°C temperature drift over 0°-70°C may be used in the design of the CLC520 circuits.

III. Using the Gain Adjust Pin

The fixed-gain differential amplifiers shown above can also be disabled with an open-collector pull-down device on pin 2. Once pin 2 is pulled below 0.4 volts, the gain will be attenuated by greater than 60dB. Again, refer to the CLC520 data sheet for a full discussion of signal attenuation vs. gain-adjust voltage. Although the forward path can be shut down in this fashion, the output pin remains a low-impedance driver: it will not be tri-stated. However, when driving several of these differential stages into an n:1 MUX, shutting down the CLC520’s gain will significantly improve the overall signal isolation at the MUX output.

An adjustable-gain differential amplifier can also be implemented with the CLC520. As discussed in the data sheet, the CLC520’s gain adjustment is intended for operation inside an AGC loop. The gain-adjust accuracy and temperature stability of the CLC520 does not support open loop operation. A companion part, the CLC522, should be used if absolute gain accuracy and gain temperature stability is desired in an open loop (no feedback to the gain adjust pin), adjustable-gain differential-amplifier application.

IV. Input Noise

The equivalent input noise of the CLC520 is set largely by the value of Rg. As shown in the data sheet, a model for the input noise voltage due to Rg is simply $R_g \cdot 18pA/\sqrt{Hz}$. For any given gain setting, scaling down the values of Rg and Rfh will reduce this input noise. Since Rfh controls the output-amplifier stability, it cannot be made too small. For a fixed Rfh, decreasing Rg will increase the signal gain. Since the input noise decreases at the same rate as the gain increases, the output noise remains nearly constant as Rg is decreased.

Figure 11 shows the measured input-referred spot-noise voltage for the differential amplifier circuit of figure 5.

Application Suggestion: Wideband Differential Coax Line Receiver

It is often necessary to transfer high-speed signals from point to point via a matched-impedance coaxial line. Figure 12 illustrates one receiver implementation using the CLC520 at a fixed gain. Since both buffers have high-impedance inputs, a simple termination across the
center conductor and shield will properly terminate the
cable allowing the differential signal to be picked-off and
amplified by the CLC520. This circuit ties the coax
shield into the local ground through a high-frequency
blocking ferrite bead. This will help prevent coupling of
high-frequency common-mode noise from the coaxial
line onto the local ground, while at the same time setting
the DC voltage and current operating point for the
CLC520 inputs. This will also act to break high-frequency
ground loops between different pieces of equipment.

Considering common-mode rejection and offset-current
drift, to keep these input termination resistors as large
as possible. Ideally, the termination resistors should be
eliminated if the bias current can be supplied by the
cable. Remember, any mis-match in the single-ended
attenuations from the center conductor’s and shield’s
source impedances into the CLC520’s input impedances
will degrade the CMRR.

**Figure 12: Differential coax line receiver**

**Application Suggestion: Video Loop-Through Amplifier**

The loop-through connection is one alternative to the
impedance-matching approach of high-speed signals.
For this approach, a high-input-impedance differential
amplifier is simply placed across the center conductor
and shield with minimal loading and no characteristic
impedance-matching. Good high-frequency common-
mode rejection and good wideband differential
amplification are essential for this application. The final
destination of this daisy-chained connection terminates
the cable in it’s characteristic impedance.

An implementation of this loop-through connection using
the CLC520 is shown in figure 13. This circuit is a
replication the circuit of figure 2 with some additional
input resistors and a shutdown control gate.

The two series 37.5Ω resistors into pins 3 and 6 act to
isolate the inputs from the cable reactance helping to
maintain high-frequency input stability. These resistors,
included with the parasitic input-capacitance to ground,
will also form a matched-impedance termination for the
cable at very high frequencies (>500MHz): well beyond
the signal frequencies of interest. The full signal level
would be available to downstream stages using this
wideband differential amplifier as a loop-through
connection.

**Application Suggestion: A Very Wideband Pulse-
Differencing Amplifier**

With the addition of several frequency-response trims,
the basic circuit figure 2 can be used to implement a
very wideband pulse-differencing amplifier. Targeting a
gain of +1V/V into a matched 50Ω load, bandwidths in
excess of 300MHz are achievable. Figure 9 shows a
typical single-sided pulse response. The input rise time
for this test is approximately 800ps. With a 1.15ns
output rise time and a 0.8ns input rise time, the amplifier’s
actual rise time is approximately 0.8ns for this 0.9V step
at the load. Very similar and well-matched results can
be achieved for both the inverting and non-inverting
inputs. Contact Comlinear for more information on
implementing this circuit.

**Figure 13: Video loop-through connection using
a wideband differential amplifier**

11 - 77
Application Suggestion: Alternative Wideband Differential Amplifiers

Although the classical single op amp differential amplifier has found wide usage, several intrinsic problems limit its performance. Both signal inputs are looking into relatively low and not necessarily well-matched impedances causing unbalanced signal-source attenuation, having the effect of degraded CMRR. Most simplified analyses assume a 0Ω source impedance in order to circumvent this problem. Furthermore, resistor inaccuracies, instead of the amplifier itself, will typically dominate the CMRR. These resistors and the amplifier's open-loop gain will determine the differential-to-single-ended conversion carried out so well by the CLC520.

However, a classical single-amp differential amplifier combined with a pair of wideband, low-output-impedance buffers can be made to approach the performance of the CLC520. This approach may be preferred if lower input noise, lower power dissipation and improved DC-drift characteristics are worth a higher number of parts, lower differential bandwidth and the necessary precise resistor-matching. Figure 15 provides an example of a single-amp differential amplifier using two buffers from a CLC114 quad buffer and a low-gain op amp with a differential gain of +1V/V.

The two input-buffers provide many of the same advantages found with the CLC520 inputs. Any of the input terminations described for the CLC520 may be used here as well. The optional 500Ω resistor to ground on the output of the non-inverting buffer provides a means of matching the loads seen by both buffer outputs. This load matching will improve the high-frequency response-match. The four 250Ω resistors should be matched as closely as possible since any mis-match will degrade the CMRR. The recommended low-gain differencing amplifier may be chosen from the following selection of Comlinear's wideband low-gain amplifiers.

CLC420 - Unity-gain stable voltage-feedback amplifier
This part will provide the best CMRR and DC accuracy

CLC402 - Low-gain high-accuracy current-feedback amplifier
Lower CMRR than the CLC420 with wider bandwidth and better fine-scale, pulse-settling accuracy.

CLC502 - Similar to the CLC402 but with an output-clipping feature

CLC410 - Intermediate performance, low-gain, current-feedback amplifier. This part also includes a shutdown feature and provides the best dG/d<j> for composite video applications.

CLC409 - Very wideband, low-gain, current-feedback amplifier.

All of these parts are optimized for the 250Ω feedback resistor shown in the circuit of figure 15.

Conclusion

As operating speeds have increased, the need for a wide-bandwidth high-CMRR differential amplifiers has increased. Comlinear's CLC520 & CLC522 provide all of the required building blocks integrated into one part. Although intended for adjustable gain requirements, operating the CLC520 at a fixed gain is perfectly acceptable and preferable in a differential receiver application. Signal bandwidths in excess of 150MHz over a wide range of gains, along with CMRR exceeding 60dB through 10MHz, and two matched high-impedance inputs provide all the essential requirements for wideband differential amplification. In some applications using wideband, low power buffers and a standard single op amp differential amplifier topology offers certain advantages over the CLC520 approach.
Application Note OA-19

Wideband Op Amp Capable of \( \mu \)Power Operation

Michael Steffes
The CLC505 is a current-feedback operational amplifier with an externally-adjustable supply current whose AC performance can be tuned to meet the precise requirements of many high-speed applications. The CLC505 provides a small-signal bandwidth of 150MHz (AV=+6) while drawing 9mA supply current from ±5V power supplies. Reducing the supply current to 1mA decreases the bandwidth by only a third; 50MHz (AV=+6). Please refer to the CLC505 data sheet for a full performance description over the 1mA to 9mA supply current range. The following application note is intended to supplement the CLC505 data sheet describing its operation with quiescent supply currents at or below 1mA.

**Frequency Response Dependence on Supply Current**

Application note OA-13 describes the internal topology of a current-feedback amplifier and the dependence of its loop gain (and hence bandwidth) on the inverting-input impedance. For an ideal current-feedback amplifier, this impedance is zero and the amplifier's frequency response is completely independent of the signal gain. As the supply current of the CLC505 is reduced below the 1mA region, the inverting-input impedance increases to such a degree that its effect on the loop-gain begins to dominate. To understand the impact of this impedance, as well as a similar increase in the output impedance (Ro) at low supply currents, the amplifier's internal block diagram, figure 1, and resulting transfer function are shown. This analysis considers only the non-inverting op amp configuration but a similar result is obtained for the inverting configuration.

An understanding of the transfer function given in equation 1 is the central point of this discussion. The supply current's dependence enters into this equation through the three internal terms, Rf, Ro, and Z(s). Rf represents the output impedance of the unity-gain buffer found between the amplifier's inputs, while Ro represents the output impedance of the output voltage buffer. Z(s) is the frequency-dependent transimpedance gain which converts the error current (ierr), flowing through the inverting input, to a voltage which is buffered to the output.

![Figure 1: Low Current CLC505 analysis topology](image)

Eq. 1

\[
\frac{V_o}{V_o} = \left(1 + \frac{R_f}{R_g}\right) \left(1 + \frac{R_o}{R_g}\right) \left(1 + \frac{1}{R_L}\right) \frac{1 + \frac{R_o}{R_g}}{z(s)}
\]

where:

\[
1 + \frac{R_f}{R_g} \rightarrow \text{desired noninverting signal gain}
\]

\[
\frac{R_o}{1 + \frac{R_f}{R_g}} \rightarrow \text{will set a limit to the high frequency attenuation as the forward transimpedance gain, Z(s), become very small.}
\]

\[
\left(1 + \frac{R_f}{R_o}\right) \left(1 + \frac{R_o}{R_f}\right) + R_o \left(1 + \frac{R_f}{R_o}\right) = \frac{1}{\text{Loop Gain}}
\]

Both the inverting input and the output pins are voltage-output structures consisting of symmetric (PNP and NPN) emitter followers (ref. 1), very similar to a Class AB power buffer (ref. 2, p 293). Emitter-follower outputs show an output impedance that is directly proportional to the operating temperature (K) and inversely proportional to the transistor's quiescent current (Re = Vt/In, Vt = kT/q, ref. 2, p 398). As the supply current decreases, the portion of the supply current allocated to these stages also decreases causing an increase in both the inverting input impedance, Rf, and the output impedance, Ro. Decreasing the supply current will also increase the DC open-loop gain, ZOL, while decreasing the dominant pole frequency, w0. However, the product of ZOL·w0 remains relatively constant over supply current and temperature.

From the transfer function shown in equation 1

\[
\text{Let } 1 + \frac{R_f}{R_g} = \text{desired signal gain}
\]

\[
z(s) = \frac{Z_{OL} \omega_0}{\omega + \omega_0} \text{-single pole, forward transimpedance gain}
\]

\[
z_f = \left(1 + \frac{R_f}{R_g}\right) \left(1 + \frac{R_o}{R_f}\right) + R_o \left(1 + \frac{R_f}{R_o}\right) \text{ feedback transimpedance; this is the inverting error current, i_{err} resulting from } V_o
\]

\[
\text{Loop gain } = \frac{z(s)}{z_f}
\]
Rewriting Equation 1 in these terms

\[
\frac{V_o}{V^+} = A_v^+ \left( 1 + \frac{R_o}{A_v^+} \frac{s + \omega_o}{Z_{OL} \omega_o} \right) \left( 1 + \frac{1}{Z_i(s + \omega_o)} \right)
\]

Manipulating this into standard form

\[
\frac{V_o}{V^+} = \frac{R_o}{Z_i} \left( s + \omega_o \right) + \frac{A_v^+ Z_{OL}}{Z_i} \frac{s + \omega_o}{Z_{OL} \omega_o} + \frac{Z_{OL} \omega_o}{Z_i}
\]

Let \( A_v^+ Z_{OL} >> 1 \), \( Z_{OL} \gg 1 \)

then

\[
\frac{V_o}{V^+} = \frac{R_o}{Z_i} \left( s + \frac{A_v^+ Z_{OL}}{Z_i} \right)
\]

Eq. 3

as \( s \to 0 \), DC gain, \( \frac{V_o}{V^+} = A_v^+ \)

as \( s \to \infty \), high frequency gain, \( \frac{V_o}{V^+} = \frac{R_o}{Z_i} = A_{\text{min}} \)

Note that the zero frequency shown in equation 3 is at a significantly higher frequency than the pole frequency. Once the operating frequency approaches this zero frequency, equation 3 predicts a minimum gain, \( A_{\text{min}} \). This is generally not observed in practice, since the zero frequency of equation 3 is typically much higher than the frequencies at which \( R_i \) and \( R_o \) start to show a normal emitter-follower inductive characteristic. To simplify this analysis, the inductive characteristics of \( R_i \) and \( R_o \) have been neglected. It should be noted that the inductive characteristics will continue to roll off the closed-loop response with attenuations much greater than that predicted by \( A_{\text{min}} \) at high frequencies. The zero shown in the transfer function of equation 3 will be neglected with the rest of this discussion focused on the closed-loop pole frequency.

Looking at equation 3 again, the closed-loop response pole will be set by \( (Z_{OL} \cdot \omega_o)/Z_t \). As the supply current is changed, the \( Z_{OL} \cdot \omega_o \) product remains relatively constant. Figure 2 shows the typical open-loop forward transimpedance gain, \( 20 \log |Z(s)| \), plotted over frequency as the supply current is varied. Figure 3 shows this same forward open-loop gain at 1 mA supply current plotted over the full military temperature range. As long as these forward gain responses fall on the same line in the 20dB/decade roll-off region, the \( Z_{OL} \cdot \omega_o \) product remains constant.

With a constant \( Z_{OL} \cdot \omega_o \) term, the only element setting the bandwidth in the transfer function of equation 3 is the \( Z_t \) expression, equation 2. In general, it is advantageous to make \( Z_t \) as small as possible which will increase the loop gain and as a result improve harmonic distortion and extend the bandwidth. The limit to the reduction of \( Z_t \) comes when higher order poles of \( Z(s) \) degrade the phase margin at the unity-gain crossover of the loop gain. For a given supply current and desired gain, decreasing \( R_i \) and increasing \( R_L \) will decrease \( Z_t \). An important limitation on decreasing \( R_i \) is the available output current drive. For the non-inverting configuration, \( R_t + R_g \) appears as an additional load in parallel with \( R_L \), while for the inverting configuration, only \( R_t \) appears as an additional load in parallel with \( R_L \).

![Figure 2: 20log|Z(s)| at different supply currents](image)

![Figure 3: 20log|Z(s)| at 1mA = I_{cc} over temperature](image)
Equation 4 emphasizes the gain dependence of $Z_t$. At low supply currents, $R_i$ becomes so large (soon at 1 mA) as to cause the first term of equation 4 to dominate. This part of the feedback transimpedance expression is directly related to the desired signal gain, $A_v$. As the gain is increased, $Z_t$ increases, decreasing the bandwidth. This bandwidth dependence on gain is analogous to that observed with voltage-feedback amplifiers. As such, for configurations which set the first term of equation 4 to be the dominant contributor to $Z_t$, a gain-bandwidth (GBW) product characteristic will be observed. Figure 4 shows a test circuit used to measure the GBW as the supply current is decreased from 1 mA to 100 μA over gains of +5, +10, and +20. At very low supply currents, slight DC-output currents due to offsets can change the AC performance. For this reason, the output DC-blocking capacitor was used to limit output DC currents.

For the 1 mA case, equations 2 and 3 were used to predict the small-signal -3dB bandwidth at the three gains of +5, +10, & +20.

With $R_p = 300 k\Omega$, $I_{cc} = 1 mA$, $R_i = 500 \Omega$, $R_o = 50 \Omega$ and approximate $Z_{OL\cdot w_o}$ product = $2\pi 120 E9$

Compute $Z_t$ from equation 2 and expected -3dB bandwidth from equation 3.

The computed and measured results are shown in Table 1.

</tbody>
</table>

The test results are in good agreement with the simplified analysis of figure 1 at the highest gain tested, $A_v = +20$. At lower gains, several effects combine to extend the bandwidth beyond that predicted by this simplified analysis. Specifically, all of the additional higher frequency poles of the open loop response can come into play at lower gains. These include both the inductive characteristics of the two output impedances and higher order poles for $Z(s)$. This has the effect of decreasing the phase margin from the theoretical $90^\circ$ assumed by the single pole analysis. Phase margins less than $90^\circ$ but greater than $60^\circ$ will extend the closed-loop bandwidth without peaking.

An additional effect serves to increase the measured bandwidth as the desired signal level is increased. As the frequency of operation increases (or as fast rise time signals are applied), an increase in the steady-state inverting-stage current is observed due to the increased $I_{err}$ required when operating at these higher frequencies with reduced loop gain. This increasing error current, as the input is swept over higher frequencies, decreases the inverting input impedance. This frequency and signal level
dependence of $R_t$ will decrease the value for $Z_t$, increasing the loop gain and extending the bandwidth. This effect is particularly pronounced when the $R_t$-$A_v$ term becomes a large part of the total $Z_t$ expression, at relatively high non-inverting or inverting gains. Under these conditions, the bandwidth actually increases as the signal level is increased. Figure 6 shows this effect for the $A_v=+20$ case of Fig. 4 with $I_{cc} = 1$mA.

$$\text{Optimum } R_f = \frac{R_t R_o (A_v^2 - 1)}{1 + \frac{R_o}{R_L}} \quad \text{Eq. 5}$$

Table 2 shows the required information to predict a gain-bandwidth product vs. supply current. At each supply current, the internal parameters ($R_t$, $R_o$, and $Z_{OL}$-$w_o$) are shown. From this, an optimum $R_f$ can be calculated using equation 5. The measured small-signal bandwidth and GBW are then recorded. The measured -3dB bandwidths shown in table 2 agree very closely with those predicted from $Z_{OL}$-$w_o$/Z$_i$ (evaluating this expression from the data given in this table and equation 2 for $Z_i$).

This estimate of GBW vs. supply current represents a very conservative estimate. As the signal gain is decreased from $A_v=+20$V/V, the GBW will increase as shown in table 1. In addition, the measured bandwidth would increase as signal level is increased, as discussed earlier, up to the point that output-stage drive current and slew limits come into consideration. The supply current and resulting GBW of table 2 are plotted in figure 7. This GBW should be taken as a minimum achievable value and a good starting point for estimating the bandwidth capability of the CLC505 at very low supply currents. A PSPICE simulation macromodel available from Comlinear can be used to test the performance under different operating conditions. This macromodel reasonably simulates most of the effects discussed earlier. Transient simulation will even show the improved rise times at higher gains as the signal swing is increased.

A common way to illustrate the wideband capability of low-power amplifiers is through a MHz-per-mA figure of merit. Figure 8 shows the same data as figure 7 with boundary regions for decades of MHz/mA shown. Two low-power Maxim op amps are also shown that claim superior MHz/mA performance. Although certainly capable parts, the Maxim amplifiers are about a decade lower in performance than the CLC505. The CLC505, along with several other Comlinear wideband current-feedback amplifiers (such as the CLC406), push strongly above the 100MHz/mA barrier. The discussion thus far has assumed ±5 volt supplies. As will be discussed later, single supply operation is also possible.

Secondary Effects of Low Supply Current Operation

Besides having a profound effect on the small signal AC performance, low supply current operation of the CLC505 will also modify most other performance characteristics. The most drastic effect is on the available output current. At 1mA supply current, the CLC505 data sheet guarantees ±5mA at 25°C. This specification should be scaled down proportionately for operation below 1mA. The non-inverting slew rate is retained with very low power levels due to a slew enhancement circuitry in the input buffer stage (e.g. at 1mA supply current, SR = 500V/\mu s for the particularly demanding condition of \(A_v=+2\)). Both of the input bias currents will decrease with supply current but the input offset voltage and temperature drift will become more pronounced. Recall that, for a current-feedback topology, the two input bias current terms are unrelated in both magnitude and polarity. Bias current cancellation to an offset-current specification is therefore ineffective. Please refer to the CLC505 data sheet for more information on these DC error terms at 1mA.

The most subtle effect is perhaps found with the noise performance. As \(I_{cc}\) is reduced, all of the amplifier’s input referred noise terms show an increase in their 1/f noise corner frequencies. Also, an additional gain term for the inverting noise current becomes appreciable. Specifically, the inverting input impedance acts as an additional impedance gain for the inverting bias current noise. The noise model discussed in application note OA-12 (Noise Analysis for Comlinear’s Current-Feedback Amplifier’s) does not consider this effect and would therefore understate the total output noise. The simulation macromodel will, however, show the correct output noise including this effect.

Taking Advantage of the Voltage Feedback Characteristic

Most of the design techniques developed for voltage-feedback amplifiers are applicable to the CLC505 operating at or below 1mA supply current. One of the standard applications for a voltage-feedback amplifier, that is not directly possible with a current-feedback part, is a simple integrator with direct capacitive feedback. Changing the feedback resistor to a capacitor and moving to the inverting integrator configuration will result in the following circuit, figure 9, and transfer function.

![Analysis circuit for inverting integrator](image-url)

Figure 9: Analysis circuit for inverting integrator
Neglecting the high frequency zero due to $R_o$

$$\frac{V_o}{V_i} = \frac{-1}{sR_2C_i \left( 1 + \frac{1}{2(s)} \left( \frac{R_o}{R_i/R_g + 1} + R_o \right) \right) \left( S + \frac{1}{sR_i/R_g + R_o/R_L} \right)}$$

Should set feedback transimpedance zero < higher order poles of $Z(s)$

$$\frac{1}{C_i \left( R_i/R_g + R_o/R_L \right)} < 2\pi(10 \rightarrow 20\text{MHz}) \text{ for } I_{CC} \leq 1\text{mA}$$

Also, high frequency feedback impedance should be > 1kΩ

$$R_i \left( \frac{R_o}{R_i/R_g + 1} + R_o \right) > 1\text{kΩ}$$

Figure 10 shows a test circuit to demonstrate this integrator operation, while figure 11 shows the resulting integration of a square wave (100kHz) input to an output triangle wave. Again the simulation macromodel for the CLC505 is very effective for analyzing the performance of these types of circuits.

Figure 10: Low power integrator test circuit

Figure 11: Integrator output to square wave input

Figure 12 shows the simulated gain and phase for the integrator shown in figure 10. Note that the DC gain of 66dB is comparable to other high-speed voltage-feedback amplifiers (such as the CLC420) while the supply current for this integrator is a very low 500µA.

Figure 12: Integrator frequency response

μPower Active Filters

To implement the Sallen-Key type of active filters, it is generally desirable to have an amplifier bandwidth at least twenty times the desired cutoff frequency. It is also desirable to operate the amplifier at relatively low gains. Figure 13 shows a test circuit used to demonstrate the CLC505’s capability of implementing very low-power single-supply high-frequency active filters.

Figure 13: Single supply μpower active filter

For low-power single-supply operation, all of the signal nodes need to be AC coupled. The three 0.1µF capacitors provide this function. This allows the non-inverting input pin to be biased at a midpoint between the supply pins, +3V in this case. The capacitors also prevent any DC currents from flowing in the output pin and reduce the DC amplifier gain to 1, which will hold the output pin DC operating point equal to the non-inverting input (centered between the supply pins.) At least 6 volts across the part’s supply pins is required to give some signal swing capability at the input.
stage from common-mode input range considerations. The amplifier's AC gain has been set for +2 and the filter components have been adjusted to allow for the amplifier's bandwidth (ref. 3).

Figure 14 shows the frequency response for just the amplifier. At this very low power and gain some peaking due to a loss of phase margin is observed. This will not effect the filter performance however. The 9MHz bandwidth is more than adequate to implement the desired 400kHz Butterworth low-pass filter. Figure 15 shows the measured filter frequency response. The desired cutoff was achieved precisely. The loss in rolloff at higher frequencies arises from a direct signal coupling to the output through the filter components after the amplifier has stopped controlling the output voltage.

Conclusions and Caveats

The CLC505 adjustable supply current op amp offers one of the highest MHz-per-mA performance levels available in a monolithic amplifier. A simplified analysis can do a good job of predicting the gain-bandwidth product under a variety of supply current, gain, feedback resistor, and loading conditions. A PSPICE simulation model available from Comlinear does an even better job of predicting performance over a wide variety of conditions. Although the internal topology of the CLC505 uses a current-feedback approach, at very low supply currents this part may be treated more like a voltage-feedback amplifier having a gain-bandwidth product. Very high-speed integrators and active filters may be implemented at exceptionally low supply currents.

Due to leakage effects, the part-to-part tolerance on supply current for a fixed R_p becomes greater as the desired nominal supply current is decreased. At R_p=300kΩ, Comlinear guarantees a maximum 1.3mA supply current at 25°C from a nominal 1mA value. If a closer tolerance at this, or lower, supply currents is required, please contact Comlinear for further information.

Current Feedback
Myths Debunked

Arne Buck
Mystery needlessly surrounds the operation and use of current feedback operational amplifiers. Many engineers refuse to design with these op-amps due to misunderstandings which are easily rectified.

Much has been written to date on the internal circuitry of current feedback op-amps. These open-loop “tutorials” obfuscate how current feedback works in a closed-loop circuit. Practical op-amp circuits are closed-loop feedback systems which yield to classical control theory analysis. Analog circuit designers are comfortable with voltage feedback op-amps in a closed-loop circuit and with the familiar ideal op-amp approximations feedback affords. It will be shown that current feedback op-amps can be analyzed in an analogous fashion. Once this closed-loop similarity is appreciated, it is easy to see that most circuits commonly built with voltage feedback op-amps can be realized with a current feedback op-amp, and with better results at high frequencies.

Refer to figure 1 to review the open-loop terminal characteristics of a voltage feedback amplifier. Ideally the non-inverting input impedance is infinite, as is the inverting input impedance. The output is a voltage source, the output impedance of which is zero. This voltage source is controlled by the potential difference between the two op-amp input terminals. This is the error voltage, hence the term voltage feedback. Feedback will drive the error voltage to zero. The open-loop dynamics are contained in $A(s)$. This $A(s)$ is a dimensionless gain, often represented in units of volts per volt or decibels.

![Voltage Feedback Op Amp Inverting Gain](figure2)

A typical voltage feedback circuit is shown in figure 2, the inverting amplifier. The transfer function is developed from the following equations:

$$V_1 = 0, \quad V_o = -A(s)V_2, \quad V_o/V_1 = (V_2 - V_o)/R_2.$$  

As $A(s)$ approaches infinity, the closed-loop gain is $-(R_2/R_1)$. The frequency response of the closed-loop circuit is determined by the denominator of the transfer function. Both the noise gain $(1 + R_2/R_1)$ of the circuit and the frequency-dependent source ($A(s)$) appear in the denominator, linking the closed-loop gain and bandwidth.

![Voltage Feedback Op Amp Assumptions](figure1)

![Voltage Feedback Op Amp](figure4)

The familiar Bode plot of this circuit is shown in figure 3. The amplifier is typically compensated with a dominant low-frequency pole to ensure stability down to a specified minimum gain, often unity. In the region where the one-pole approximation of the open-loop response is valid, the phase is around -90 degrees. This is the gain-bandwidth product region. The intersection of the zero-slope noise gain line and the open-loop gain curve determines the closed-loop system -3dB bandwidth. A high gain circuit will have less bandwidth than a lower gain circuit. As the circuit moves to lower gains, bandwidth increases, phase margin is lost and stability suffers.

![Voltage Feedback Op Amp](figure3)

The open-loop terminal characteristics of a current feedback amplifier are depicted in figure 4. There is a unity-gain buffer between the two op-amp inputs. This buffer ideally has infinite input impedance and zero output impedance.
Thus the non-inverting input impedance of the current feedback op-amp is infinite, and the inverting input impedance is zero. The output is a voltage source, so the output impedance is zero. This voltage source is controlled by the current out of the inverting input. Feedback forces the error current to zero. The open-loop dynamics are determined by $Z(s)$. This $Z(s)$ is a current controlled voltage source which has units of transimpedance, ohms.

The inverting amplifier employing a current feedback op-amp is shown in figure 5. The transfer function is derived from the following equations:

$$V_i = 0, \quad V_o = Z(s)I_{inv}, \quad (V_i / R_i) + I_{inv} = -(V_o / R_2)$$

As $Z(s)$ approaches infinity, the closed-loop gain is $-(R_2 / R_1)$. Notice that only the feedback resistor appears in the characteristic equation, in the term with $Z(s)$. The closed-loop gain has been decoupled from the frequency response determining term of the transfer function. Only the feedback resistor affects the closed-loop frequency response.

A Bode plot for the circuit is shown in figure 6. A current feedback amplifier is also compensated with a dominant low-frequency pole. This pole is usually at a higher frequency than that of a voltage feedback op-amp. A current feedback op-amp is commonly compensated for maximally flat response at a specified closed-loop gain and with a specified feedback resistor. The phase is approximately -90 degrees where this one-pole approximation is valid. The ideal current feedback op-amp does not have a gain-bandwidth product. The closed-loop bandwidth is determined by the feedback resistor, not the closed-loop gain. One could entertain the idea of a “feedback-resistor-bandwidth” product. The intersection of the zero-slope feedback resistor line and the open-loop transimpedance curve yields the closed-loop -3dB bandwidth. A circuit with a higher feedback resistor will have reduced bandwidth. This is a good way to overcompensate the current feedback op-amp. A feedback resistor of twice the manufacturer’s recommended value will cut the circuit bandwidth in half. As the feedback resistance, or impedance, is reduced to a lower value, there is a loss of phase margin. As can be seen from the transfer function in figure 5, if the negative of the loop transmission, $(R_2 / (Z(s))$, equals -1 the loop is unstable.

The design trade-offs between current feedback and voltage feedback differ. Voltage feedback allows freedom of choice of the feedback resistor (or impedance) at the expense of sacrificing bandwidth for gain. Current feedback maintains high bandwidth over a wide range of gains at the cost of limiting the feedback impedance.
For example, a common error in using a current feedback op-amp is to short the inverting input to the output in an attempt to build a voltage follower. This circuit will oscillate. The circuit is perfectly stable if the recommended feedback resistor is used in place of the short. Similarly, an integrator is commonly accomplished by placing a capacitor between the inverting input and output. At high frequencies a capacitor has a low impedance and can easily have an impedance less than that required for stability. The proper feedback resistor in series with the feedback capacitor will stabilize the amplifier, and introduce a high frequency zero into the integrator transfer function.

Another aspect of current feedback op-amps which causes much consternation is the low open-loop inverting input impedance. This feature, which causes the decoupling of closed-loop gain and bandwidth, is often viewed as making current feedback op-amps unsuitable for use as differential amplifiers. In fact, the low inverting input impedance can result in a better high-frequency differential amplifier than a similar circuit built with a voltage feedback op-amp.

First, consider the closed-loop driving-point impedance of an op-amp, regardless of the nature of the error signal. The circuit and equations to find this closed-loop impedance are shown in figure 7. The resistor, R, is the open-loop inverting input impedance. Note that R is simply a resistance. A voltage feedback amplifier will have an R approaching infinity; in a current feedback op-amp R approaches zero. A test current, \( I_T \), is applied to the inverting input and the inverting node currents are summed. To find the closed-loop inverting input impedance of either amplifier type simply substitute the proper form of the output voltage, \( V_o \).

In the case of the voltage feedback op-amp, \( V_o = -V_2 A(s) \) for this circuit. The result, \( Z_{inv}(s) \), is in figure 8. The familiar result is that when \( A(s) \) approaches infinity, the incremental inverting impedance approaches zero. This is the incremental or virtual ground on which much first-order op-amp analysis is based.

The output voltage is derived differently in the current feedback op-amp. When \( V_o = -V_2 (Z(s) / R) \) is substituted, the result is in figure 8 also. It can be seen that two mechanisms force the inverting input impedance to a low value, ideally zero. When \( Z(s) \) is very large, \( Z_{inv}(s) \) goes to zero. In addition, as R goes to zero so does the closed-loop inverting input impedance. The topology of the input buffer keeps R small to very high frequencies. Thus a current feedback op-amp can have a better virtual ground at the inverting input than a voltage feedback amp, especially at high frequencies.

A summary of the above discussion is tabulated in figure 9. The voltage difference between the input terminals is zero. Voltage feedback drives this difference to zero. The current feedback amplifier input buffer forces the two input terminals to equal voltages. Both amplifier types have a high non-inverting input impedance, so the non-inverting current is small. A voltage feedback op-amp has a high open-loop inverting input impedance, thus the inverting current approaches zero. Current feedback forces the inverting current to zero. Both op-amps display similar input voltage and current characteristics. Only the mechanism forcing these to zero differs.
It can now be seen that from a closed-loop standpoint both current and voltage feedback op-amps allow the same ideal op-amp assumptions to be made. Voltage feedback has a gain-bandwidth product which limits the lowest stable gain. Current feedback displays a “feedback-resistor-bandwidth” product which limits the lowest stable feedback impedance.

The inverting input impedance of an ideal voltage feedback op-amp in a closed-loop circuit is zero. Feedback accomplishes this by dividing a high open-loop impedance by a high loop gain. The open-loop inverting input impedance of an ideal current feedback op-amp is zero. A practical current feedback op-amp has a finite inverting input impedance, less than 100Ω. Feedback reduces this further by dividing the initially low open-loop inverting input impedance by the loop transmission. The result is a better incremental ground at the inverting input to very high frequencies.

As both amplifier types are used in closed-loop topologies, the same methods of analysis are equally applicable. Now that this is seen, current feedback op-amps can easily be designed into amplifiers of any arbitrary gain (inverting and non-inverting), integrators, differential amplifiers (figure 10), and current-to-voltage converters, commonly known as transimpedance amplifiers (figure 11).
Selecting and Using High-Speed Track and Hold Amplifiers

David Potson
Scott Evans
INTRODUCTION

High-speed track and hold (T/H) amplifiers are essential elements of high-performance flash A/D systems. In order to realize the performance improvements that a T/H can achieve, a knowledge of how to select the proper device and how to properly apply it is necessary. This requires a clear understanding of how the various device specifications impact system performance. This application note will discuss these issues in relation to the high-speed architecture of figure 1. The latter part of the application note should be referenced for a detailed definition of each specification.

![Diagram of a high-speed T/H amplifier](image)

**Figure 1:** Block diagram of a high-speed T/H amplifier.

TIMING CONSIDERATIONS

The first consideration in selecting a T/H is to find one that will be fast enough for the intended A/D conversion system. There are two common flash conversion systems where T/Hs are frequently found. The simplest is the single-stage flash converter of figure 2. It is instructive to analyze the timing relationships of this system. A more complicated system, the sub-ranging A/D, is used where higher resolution is required at high sample rates. The timing relationships of this latter system are more complex and will not be discussed in this application note, although the concepts presented are valid in these systems as well.

![Diagram of a single-stage flash A/D converter system incorporating a T/H amplifier](image)

**Figure 2:** Block diagram of a single-stage flash A/D converter system incorporating a T/H amplifier.

In a timing analysis, there are two points of interest. The first is the T/H clock rate and duty cycle, and the other is the timing relationship of the A/D clock with respect to the T/H clock. The A/D clock duty cycle is also important, but is independent of the T/H and so will not be discussed.

The T/H worst-case clock rate and duty cycle are obtained by independently determining the minimum required “track” and “hold” times. Since sufficient time must be provided for all events to take place within their respective periods, the timing equations can be determined from the waveforms of figure 3. These are:

\[ t_{\text{track}} = t_{\text{aco}} + t_{\text{dht}} - t_{\text{ead}} - t_{\text{da}} \]  \hspace{1cm} (1)

\[ t_{\text{hold}} = t_s + t_{\text{a/d}} - t_{\text{dht}} + t_{\text{ead}} + t_{\text{da}} \]  \hspace{1cm} (2)

where \( t_{\text{a/d}} \) is the aperture time of the A/D and \( t_{\text{aco}} \) is the acquisition time of the T/H while driving the capacitive input of the A/D—not the value which is specified into a purely resistive load. Remember that \( t_{\text{ead}} \) can be either positive or negative, depending upon the specific T/H. The minimum T/H cycle time is simply the sum of the above equations:

\[ t_{\text{cycle}, \text{min}} = t_{\text{aco}} + t_s + t_{\text{a/d}} \]  \hspace{1cm} [Ideal case] \hspace{1cm} (3)

Note that the three delay terms are “pipelined” out of the system.

Operation of the T/H at this minimum cycle time presents a problem, though, which is caused by manufacturing variations of the T/H and A/D. Again, since sufficient time must be allowed for all events, the worst-case \( t_{\text{track}} \) and \( t_{\text{hold}} \) times should be used in the system set-up if the system must work without timing adjustments. Minimum \( t_{\text{track}} \) is found by setting all positive terms in equation 1 to their maximums and all negative terms to their minimums. Likewise for equation 2. Now, however, the sum of equations 1 and 2 no longer equals equation 3. A more accurate expression for the minimum cycle time is,

\[ t_{\text{cycle}, \text{min}} = [t_{\text{aco}} + t_s + t_{\text{a/d}}] + [\Delta t_{\text{dht}} + \Delta t_{\text{ead}} + \Delta t_{\text{da}}] \]  \hspace{1cm} (4)

The terms within the second set of brackets all cause the minimum cycle time to increase from the ideal value given by the first set. To set the system for maximum speed, the minimum cycle time is first computed from equation 4 and then equations 1 and 2 are used to set clock duty cycle while keeping in mind worst-case conditions.

Although they serve as useful analytical tools, equations 1, 2, 3, and 4 cannot in practice be used by themselves to arrive at a timing setup. This is because T/H manufacturers do not guarantee some of the delay terms and, when delay terms are guaranteed, just a maximum or a minimum is given. In addition, some A/D manufacturers do not guarantee \( t_{\text{a/d}} \). This all points to the necessity of designing sufficient margin into the system timing. The best that can be done is to obtain typicals where no data is given and then to assume “reasonable” variations for those delays where only one extreme is guaranteed. Finally, the system can be tested to determine sensitivity to timing errors by varying T/H clock duty cycle and monitoring the change in performance. If an extreme sensitivity is found, system timing can be altered.

A similar analysis to that above shows that the conversion edge of the A/D clock should be positioned in relation to the hold edge of the T/H clock according to the following equation:

\[ t_{\text{edge skew}} = t_{\text{ead}} + t_{\text{da}} + t_s + t_{\text{gr}} - t_{\text{ead}, \text{a/d}} \]  \hspace{1cm} (5)
where $t_{GR}$ is the group delay of the RC filter formed by the A/D input capacitance and the series damping resistor, and $t_{EAD, A/D}$ is the effective aperture delay of the A/D. The same definition of effective aperture delay as applies to T/Hs is assumed for the A/D. A positive value for $t_{EAD, A/D}$ indicates that the T/H clock edge should precede the A/D clock edge.

The same problems noted above exist also with the application of equation 5. Only typical values are usually given for $t_{DA}$ and most A/D manufacturers specify a maximum for $t_{EAD, A/D}$ when a minimum is what is needed.

A versatile circuit for generating both the T/H and A/D clocks is shown in figure 4. Although somewhat complex, this circuit has the advantage of being able to independently set the duty cycles of both clocks and the skew between them. This may be of benefit in those situations where only one design iteration of the PCB will be performed, but it is still desired to make last-minute changes in the timing for optimum performance. Of course, if this is unnecessary, or if the A/D duty cycle is not critical, the circuit can be greatly simplified.

**LINEARITY AND DYNAMIC ACCURACY**

Linearity and dynamic accuracy form another set of specifications usually evaluated in conjunction with the timing specifications. DC linearity is of some interest since a device cannot be relied upon to deliver better dynamic accuracy than it can at DC. More importantly, designers of high-speed systems focus on the harmonic distortion specification, which is an indication of the linearity of the amplifiers within the T/H at high analog frequencies. Both of these linearity specifications describe operation in the track mode. In addition, there are specifications that apply to the hold mode which can also impact accuracy. Finally, aperture jitter is a specification describing an error source that occurs during the transition from track to hold.

**Harmonic Distortion**

Because harmonic distortion is measured with the device in the track mode, it gives only an estimate of true performance in a sampled data system. The specification includes none of the switching dynamics which occur in the dynamic sample-mode where the T/H toggles repeatedly between the track and hold modes. Actual dynamic performance, being a function of these switching dynamics, will depend on the clock signals supplied to both the T/H and A/D. When operating with con-
servatively-chosen clock signals, the T/H performance can be expected to closely approach these distortion levels given by the manufacturer. However, as the cycle time approaches the minimum as determined above, the distortion levels will worsen. Manufacturers prefer not to specify dynamic sample-mode harmonic distortion because of the difficulty of the measurement and its dependence upon more application-specific variables compared to the simple track-mode harmonic distortion test.

Part of the difficulty encountered in measuring dynamic sample-mode harmonic distortion is in finding a high-time.

flexibility in simulating various

increase acquisition and settling time because of reflec-
tions. If a transmission line is necessary, it should be

located before the T/H and the distance between the T/H

and $A/D$ kept as short as possible. If this is not possible,
a closed-loop amplifier can be used to drive the line. This,
of course, will increase cycle time because of the amplifier

settling time. Heavy loading also increases thermal tail
although this is not a problem with most A/D applications.

Also related to loading is the fact that high-speed amplifiers do not yield their best settling times when operating into the highly capacitive inputs of flash A/D converters without some assistance. Typically, this assistance is simply a series damping resistor placed between the T/H and $A/D$ as in figure 2. The value of this resistor is, of course, important in minimizing acquisition time. Too small a value will cause excessive ringing and too large a value will excessively overdamp the output. The ac-

sition time of the T/H while driving the A/D input capac-

itance is the proper value to use when computing worst-case timing.

### Hold-Mode Specifications

Hold-mode specifications that impact accuracy are droop rate and feedthrough rejection. Poor performance in these areas becomes apparent when evaluating dynamic sample mode performance. This again points to the usefulness of the above technique for evaluating T/H performance since many error sources contribute to the overall performance. These tests by themselves, however, do not pinpoint the specific cause of a problem.

### Droop Rate

Droop rate can be a source of nonlinearity because the actual droop added to each sample is a function of the sampled voltage level. In the T/H block diagram of figure 1, this behavior is attributable to the FET used to buffer the hold capacitor node. Its gate current is a function of $V_{DD}$, which is nonlinearly dependent upon the sampled level. As a target, the T/H chosen should have droop less than 1/2 lsb from the time the amplifier enters the hold mode to when the A/D completes conversion. This assessment should be done at maximum operating temperature because FET gate current increases exponentially with temperature. Furthermore, the gate current will be greatest for the most negative input level since this is where $V_{DD}$ is greatest.

### Feedthrough Rejection

Feedthrough rejection, another hold-mode specification, has the potential for degrading accuracy by causing the held voltage level to change as the analog input to the T/H continues to change. As a rule of thumb, feedthrough rejection should be $(6dB)(n+1)$ or better at the maximum analog input frequency. In this equation, $n$ represents the system accuracy in number of bits. Feedthrough rejection can degrade if power supply bypassing is not properly done. Sometimes the power supply pins for the input and output sections of the T/H are brought out separately. These devices offer superior performance since they allow the user to filter the supply line between the various sections and eliminate the power supply as an input-to-output coupling path during the hold period.

### Aperture Jitter

Aperture jitter, the last specification within this group, has its dominant effect on the output noise floor of the A/D system. This random variation in effective aperture delay causes a random error in the held level of the T/H. The conversion factor from time error to voltage error is the slew rate of the analog input signal. Larger slew rates cause larger errors. As a result, the noise floor is a function of the analog input signal frequency, $f$. Specifically, for a sine wave input, the slew rate is simply a cosine wave and its rms slope is (Reference 2):

$$\frac{dv}{dt}_{\text{rms}} = \frac{2 \pi f V_p}{\sqrt{2}}$$

(6)
where $V_p$ is the peak value of the sine wave. A given aperture jitter, $dt$, in rms, will give rise to an rms noise level of:

$$e_{n|\text{rms}} = \frac{dv}{dt|\text{rms}} (dt)$$  \hspace{1cm} (7)

Since an ideal n-bit A/D converter is expected to give an rms-signal-to-rms-noise ratio of:

$$\text{SNR} = [1.8 + 6.02n]\text{dB}$$  \hspace{1cm} (8)

for n-bit performance, T/H aperture jitter should be low enough so that the following equation is obeyed:

$$20\log_{10} \left( \frac{V_p}{\sqrt{2}e_{n|\text{rms}}} \right) \geq [1.8 + 6.02n]\text{dB}$$  \hspace{1cm} (9)

Solving for $dt$,

$$dt \leq \frac{1}{1.2 \pi f T 2^{n+11}}$$  \hspace{1cm} (10)

As an example, for 12-bit SNR with $f = 10\text{MHz}$, the aperture jitter should be less than 3.2ps rms. Intermediate frequency (IF) sampling applications place even more severe restrictions on aperture jitter. Because of its randomness, aperture jitter does not affect the dynamic sample mode harmonic distortion of the A/D system. Overall SNR will decrease beyond that determined using equation 9 because of amplifier noise, quantization noise, and distortion (Reference 3).

**OTHER PERFORMANCE ISSUES**

In choosing a T/H amplifier, the specifications covered above usually determine the selection since little can be done elsewhere in the circuit to correct problems resulting from these. Once the selection is made, a survey of the miscellaneous specifications indicates how convenient it will be to design the device into the system. This, of course, is not entirely true if the system has some unusual sensitivity to a particular miscellaneous specification, such as power dissipation in space-based systems, for example.

Offset voltage and temperature drift combine with pedestal offset and temperature drift to establish the DC offsets of the T/H. Typically, because other system components such as amplifiers and the A/D have offsets and drifts of their own, the system will incorporate an adjustment somewhere to null the initial offsets, and the drifts if it is of the self-calibrating type. Because the pedestal offset occurs only in the hold mode, it is important that the null be performed after the device enters the hold mode and before significant error caused by droop is incurred.

For some T/Hs, the pedestal offset can be dependent upon input voltage level; when this is the case, linearity can be affected. Unfortunately, this is a hidden danger since some manufacturers do not specify this effect when it is present. Poor performance here will show up during dynamic sample distortion measurements.

The effects of low bandwidth will show up in the acquisition time specification. Beyond this, frequency response will be of interest when the application is IF sampling or when the system includes precise filter functions that should be designed independent of the T/H amplifier response.

Similarly, insufficient slew rate can show up as a poor acquisition time specification and should be scrutinized when the application calls for IF sampling.

The input voltage range of the T/H should be consistent with the A/D being used since T/H amplifier performance is optimized for a given input range. Operation in conjunction with an A/D having a different range will add complexity by requiring the insertion of active components between the the T/H and A/D. Most high-speed A/D converters have a 2 volt input range either centered about 0 or -1 volt.

**Protection Circuitry**

Protection is another issue usually addressed during the design process. Although protection circuit design is specific to the devices that are to be protected, some general guidelines can be stated. Quite often the maximum input range of the A/D will either be close to that of the T/H or, more often, more restricting. Because of this, a clamp located before the T/H can be used to protect both the T/H and A/D from excessive input levels. Maximum safe input levels are usually far enough removed from the region of linear operation to allow simple diode clamping to be effective without impacting linearity.

A clamp just before the T/H cannot protect the A/D from failure of the T/H or from large T/H output voltages that might occur upon loss of the clock if the T/H is allowed to remain in the hold mode. The former problem can be simply solved by locating an additional diode clamp after the T/H. Current limit circuitry, notorious for limiting high-speed performance, can be omitted and the T/H allowed to operate directly into the clamp since activation of this second clamp implies damage has already occurred to the T/H. The latter problem, a result of droop, is avoided by forcing the T/H into the track mode on loss of the clock.

Finally, compatibility of the digital control input with a particular logic family is a matter of convenience. Some T/Hs are compatible with only one logic family while others can be configured for several.

**SYSTEM TESTING**

Once a T/H amplifier selection has been made, the device is either tested by itself in the dynamic sample mode as discussed above, or as part of the entire A/D system. Chances for success improve as the margin between specification and requirement increases. The most common tests to be used are beat frequency testing, which is useful in finding spurious and missing codes, and SNR testing, which evaluates overall dynamic system performance against that of the ideal converter SNR (References 4 and 5). Other tests exist as well for isolating particular faults.

Read Comlinear Application Note TH-06, “Track and Hold Amplifiers Improve Flash A/D Accuracy” for a discussion of the A/D system dynamic performance benefits that a T/H amplifier provides.
TRACK AND HOLD TERMINOLOGY

Acquisition Time (hold to track) is the time required for the track and hold to acquire the input signal to a specific settling precision when it switches from hold mode to track mode. It is the time from the point when the output starts changing to the point when the output has settled.

Analog Delay (input to output) is the time required for a signal to travel from the analog input to the analog output.

Aperture Jitter or aperture uncertainty is the sample-to-sample variability in Effective Aperture Delay which is caused by a small amount of noise in the switch control circuitry. Aperture Jitter changes the time at which the device goes into hold mode. Coupled with the rate of change (slew rate) of the signal at the storage capacitor, Aperture Jitter causes an error in the held output voltage. (Output voltage error = ΔV/Δt * Δt, where ΔV/Δt is the slew rate and Δt is the Aperture Jitter.)

Droop Rate is a drift in the held output voltage. It is caused by leakage currents flowing into (or out of) the storage capacitor from the switching circuit and the input stage of the output amplifier.

Effective Aperture Delay tells when the input signal is actually being sampled. It takes into account two delays: 1) the input signal transit time through the input amplifier and 2) the time needed for the switch to open after the part is given the hold command. (Conceivably, Effective Aperture Delay could be negative if the transit time through the input amplifier were longer than the delay in the switch.)

Feedthrough Rejection or analog input isolation describes how well the switch keeps the input signals from "feeding through" to the output when the device is in hold mode. It is the ratio of the signal that passes through the open switch to the signal at the analog input. Since signal feedthrough is, in part, caused by the capacitance of the switch, Feedthrough Rejection is better for low-frequency input signals. There are, of course, switching transients which feed through from the digital inputs; however, these settle out quickly and are accounted for in the Acquisition Time and Track-to-Hold Settling Time specifications.

Hold-to-Track Switch Delay is the time delay from the track command to the point when the output voltage begins to change as it starts to acquire the new signal.

Pedestal Offset or track-to-hold offset is an output offset voltage found in hold mode. It is caused by a small amount of charge injected into (or out of) the storage capacitor when the (diode bridge) switch opens. In practice, this offset is treated just as an output offset voltage.

Track-to-Hold Switching Transient is the switch-induced transient voltage which appears at the output immediately after the device switches from track to hold.

Track-to-Hold Settling Time is the time required for the Track-to-Hold Switching Transient to settle out to the point where the output is within 1mV of its final value.

Improve Flash A/D Accuracy
David Potson
Scott Evans
INTRODUCTION

The growing usage of flash A/D converters is testimony to the ever-higher sampling rates and bandwidths of high-speed systems. While this trend will, no doubt, continue, designers are now also demanding accuracy from their flash A/D systems. While this is possible at low speeds, it becomes increasingly difficult at high speeds. Specifically, at high signal bandwidths, flash A/D converters retain only a fraction of their low-speed accuracy. The solution to this dilemma is the use of a track and hold (T/H) amplifier to reduce or eliminate flash A/D errors.

FLASH A/D ERROR MECHANISMS

Flash A/D converters are so named because of their seemingly instantaneous conversion process. The architecture of the flash A/D shows this (see figure 1). Relative to other A/D architectures (such as dual slope integration or successive approximation), the flash A/D is indeed instantaneous. However, relative to the speed of high-speed analog input signals, this simplification of instantaneous conversion is not correct. Timing delays and variations which can be ignored at low frequencies become major sources of inaccuracy at high signal bandwidths.

THE TRACK AND HOLD CONTRIBUTION

Using a T/H transfers the burden of acquiring the signal from the complicated A/D input structure to the simple, single-element switch of the T/H (see figure 2). The task of digitizing the signal remains with the A/D, but now the comparators can operate on a signal level that remains constant during conversion. Most systems can benefit from this synergistic combination; fortunately, the performance improvement can be assessed quantitatively with the right test system. In the flash A/D system illustrated in this application note, for example, the signal to noise ratio was shown to improve by 17dB with the addition of the track and hold.

MEASURING T/H ACCURACY CONTRIBUTION

There are many ways to test the performance of a high-speed A/D system (see reference). The method presented here was chosen with several objectives in mind: 1) the test system must be relevant to real A/D systems as they are used in real systems, 2) it should be easy to duplicate by others, and most importantly, 3) it must be experimentally correct. The test system is shown in figure 3.

Figure 1: Simplified schematic of the flash A/D.

When the flash A/D architecture (figure 1) is reexamined in the context of wideband analog signals, several potential error mechanisms are apparent. For example, the input comparators must receive the signal simultaneously and they all must be gated or latched simultaneously. The sheer complexity imposed by the 255 input comparators of an 8-bit device suggests that this will be difficult, if not impossible, for high-bandwidth analog signals. Circumventing the problems of this complicated input structure is exactly how a high-speed T/H improves accuracy.

Figure 2: The use of a T/H transfers the burden of acquiring the signal from the complicated A/D input structure to the simple, single-element switch of the T/H.
followed by manipulation and analysis. Each approach has its
advantages and disadvantages. The first method, reconstruction
and conventional analysis, is used here because it is easily duplicated
with common test equipment and avoids the complexity involved in
acquiring and then manipulating the digital data.

Reconstruction of the digitized analog signal is straightforward: the
8-bit A/D data is converted to analog by a 10-bit D/A. The D/A's
output voltage is sent to a dynamic signal analyzer to show both the
frequency-domain and time-domain performance. The only
complexity is in the clocking scheme of the D/A converter which allows
the use of readily-available test equipment.

A divide-by-120 counter is used to generate the 200kHz D/A clock
signal from the 24MHz A/D clock. Consequently, every 120th A/D
sample is reconverted and analyzed by the test system. This produces
a beat frequency which is a function of the analog input frequency
and the 200kHz D/A clock; in effect, the beat frequency "walks
through" the input signal. The benefit of this technique is that it
provides full D/A accuracy while exercising the A/D under realistic
conditions. Also, the relatively low reconstruction clock rate permits
the beat frequency and the harmonics to appear in identical locations
for every 200kHz increment in the analog test frequency. Conse­
quently, the D/A operating conditions never change so that even
small variations in D/A performance can be ruled out. See the
section titled "Interpreting the Frequency-Domain Graphs" for a
technical explanation of this analysis technique.

THE RESULTS

Time Domain

Figure 4 shows the time-domain performance of the A/D without
and with the assistance of the T/H. The missing and spurious codes
are obvious and especially so on the enlarged scale (figure 5). These
problems typically amount to a reduction in accuracy of about
1-2 bits; the inaccuracy in some regions (zero-crossing region in
particular) is much greater—effectively reducing the A/D's accuracy
to only 4 bits or so.

Figure 4: The MC10319 is operating at a sample rate of 24MSPS and
an analog input of 2Vpp, 10.000250MHz. Serious non-linearities are
present in (a) with the CLC940 inactive. In (b), the CLC940 is activated
and the non-linearities disappear.

Figure 6: Operating at 24MSPS, a 10.005MHz, 2Vpp analog input signal
yields elevated harmonics and noise floor (a). In (b), the CLC940 is
activated and both the harmonics and noise floor are decreased,
resulting in a SNR of 48.3dB.

Frequency Domain

As important, and often more useful, is the frequency-domain
response of the system. Figure 6a shows the A/D performance with
the T/H inactivated. The signal to noise ratio is 31.3dB and the total
harmonic distortion is 32.8dB below the signal (since the distortion
is so large, noise terms, such as would be caused by aperture
uncertainty, are comparatively small). This value of signal to noise
ratio indicates an effective accuracy of about five bits.

Figure 6b shows the performance improvement seen when the T/H
is activated. The signal to noise ratio improves to 48.3dB (7.7-bit
accuracy) and the total harmonic distortion improves to ~53dB.

Figure 5: The zero-crossing region of figure 2 is expanded by reducing
the analog input frequency to 10.0000625MHz. When the CLC940 is
activated, a 12-LSB amplitude glitch is smoothed out. Lack of mono­
tonicity in other areas is likewise eliminated. Time-record averaging is
employed in both traces to eliminate noise.
INTERPRETING THE FREQUENCY-DOMAIN GRAPHS

As mentioned previously, the test system shown in figure 3 samples the analog input signal at 24MHz yet reconstructs the signal at 200kHz. This provides the advantage of operating the reconstruction D/A at full accuracy and allows higher-speed A/Ds to be accommodated. The only disadvantage of this approach is the complexity of interpreting the frequency-domain results; fortunately, this complexity clears quickly as the theory is understood.

Aliasing

The concept of aliasing is straightforward. Simply put, the spectrum of the input signal is replicated at multiples of the sampling frequency (see figure 7). It is useful to note that the original signal is composed of both positive and negative frequency components, both of which are replicated through sampling. For example, a sinusoidal signal at 1MHz which is sampled at 10MHz will appear in the frequency domain at 1MHz, 9MHz, 11MHz, 19MHz, 21MHz, etc. It will also have negative frequency domain components: -1MHz, -9MHz, -11MHz, etc.

Figure 7: The frequency domain representation of a 1MHz sine wave is shown in (a). When this signal is sampled at 10MHz, the original spectrum is replicated at multiples of the sampling rate (b).

If the analog frequency is increased, its frequency domain representation will change. For an analog input signal of 7MHz the frequency components will be found at 3MHz, 7MHz, 13MHz, 17MHz, etc. with negative components existing as well. If the frequency increases to 14MHz, frequency components will be found at 4MHz, 6MHz, 14MHz, etc. Now take an 18MHz signal; its components will be at 2MHz, 8MHz, 12MHz, 18MHz, etc. Notice that in each case, the sampled signal is replicated in the f_s/2 Nyquist band once and only once regardless of the input signal. Through the concept of superposition, this discussion can be related to the spectrum of a complex signal.

Consider an analog signal composed of the four signals described above: 1MHz, 7MHz, 14MHz, and 18MHz (see figure 8). When it is sampled at a frequency f_s, the frequency components will be spread throughout the frequency domain (as one would expect); however, in the f_s/2 range, the frequency components appear once and only once. For a sampling frequency of 10MHz, these components appear at 1MHz, 2MHz, 3MHz, and 4MHz. (Noise present at the analog input signal is aliased the same way—all of the noise, regardless of frequency, is aliased into the f_s/2 band once and only once.)

Figure 8: A complex signal having frequency components at 1MHz, 7MHz, 14MHz, and 18MHz is shown being sampled at 10MHz. The original spectrum is replicated at multiples of the sampling frequency. Note that the Nyquist band (f_s/2) contains all of the original components—each component is aliased in once and only once.

This same idea can be related directly to the test system where the analog frequency and all of its harmonics are greater than the 200kHz reconstruction frequency, but are aliased into the Nyquist band nonetheless. (In fact, the harmonics appear in ascending order due to the choice of the beat frequency.)

Signal to Noise Ratio Calculations

Signal to noise ratio is calculated as it would be for any ordinary signal but with one exception. The D/A converter functions as a zero-order hold and consequently, introduces a sinx/x characteristic having the first null at 200kHz. It is not corrected by the hardware, but fortunately, the effects of this can often be ignored since the attenuation is just 3.9dB at 100kHz (f_s/2) where the harmonics are of lesser magnitude. Also, the sinx/x characteristic reduces integrated system noise by 1.1dB. This and a 0.3dB error caused by the analyzer have been taken into account in the SNR value stated earlier.

MACROMODELS FOR HIGH SPEED AMPLIFIERS

INTRODUCTION

This application note is intended to support the PSpice macromodels for Comlinear's High Speed amplifiers. The macromodels offer the design engineer the ability to model typical amplifier circuit topologies. These models are intended to work with Pspice, but similar spice simulators can be used with the appropriate syntax modifications. The user is responsible for making those changes. The products available for simulation are summarized in the diskette's readme file using file names as shown in Table 1.

| CLC400.CIR | CLC410.CIR | CLC430.CIR |
| CLC401.CIR | CLC414.CIR | CLC501.CIR |
| CLC402.CIR | CLC415.CIR | CLC502.CIR |
| CLC404.CIR | CLC420.CIR | CLC505.CIR |
| CLC406.CIR | CLC425.CIR | CLC520.CIR |
| CLC409.CIR |

The macromodel's net lists are saved on an IBM-compatible 1.2 MByte floppy diskette in ASCII format.

QUICK START

Place the diskette in a 1.2MByte drive and execute the DIR command. To print a listing of the macromodel subcircuits type the following command:

print [\(drive:file \text{name}\)]

Comlinear suggests that files be copied to the Pspice library. If the user intends to access the diskette from a floppy drive, then the proper path must be established for Pspice. To access the macromodels from the floppy, use the Pspice include command in the circuit net list.

example: .INC A:\[file \text{name}]

UPDATE INFORMATION

The application diskette shows a revision number on the label. Please refer to this revision number when contacting Comlinear Corporation for additional assistance or model availability.

APPLICATION INFORMATION

The macromodels are configured as sub-circuits to allow easy inclusion into larger simulation files.

- Connect: NON-INVERTING INPUT
- INVERTING INPUT
- OUTPUT
- +Vcc
- -Vcc
- SUBCKT() 3 2 6 7 4

Several schematic capture software programs require a different pin order for the inputs, outputs, supplies, etc., in the subckt (name) command line. If Comlinear's models do not work properly, check to see that the order is compatible with your software. Changing Comlinear pin order in the subckt command will not effect modeling capability. You must maintain the same pin node numbers. Substitution of high speed op amps into existing designs is welcome. If satisfactory results are not obtained for current feedback op amps then Comlinear suggests that you read application note OA-13, "Current Feedback Amplifier Loop Gain Analysis and Performance Enhancements". If you have a specific design application and need help choosing a correct part for your design, contact the application department of Comlinear.

These macromodels accurately simulate the typical performance for the following parameters:

DC Effects

- VIO, IBI, IBN
- Supply current vs. supply voltages
- Common Mode Input/Output Voltage range.
- Load current from supplies

AC Effects

- Frequency response vs. gain & load
- Open loop gain & phase
- Noise
- Small signal Input/Output Impedance.
- CMRR

Time Domain

- Rise and fall times
- Slew Rates

Special Features

- Output limiting
- Supply current adjustment
- Offset voltage adjustment
- Disable/enable time

Performance characteristics that are NOT modeled include:

- Breakdown & leakages due to excessive Vcc
- Part to Part variation
- Variation in performance vs. temperature.
- Fine scale settling performance
- Harmonic distortion
- Differential gain
- Differential phase
- Thermal tail
- Overdrive recovery time
- PSRR

12 – 4
LIMITATIONS

The macromodels were developed from measured data to match the actual performance on each of the devices modeled. Typical simulation results should closely match the characteristic performance plots shown in each of the op amp data sheets. Slight variations from the data sheet plots can be expected based on part to part variation and slight test fixture parasitics. Board and component parasitics, if known, should be included in any simulation for the most accurate performance. These macromodels are intended to provide the designer an easy means of evaluating full circuit performance with a variety of external components, and operating conditions. Good engineering practice advocates that a physical implementation of the desired circuit also be implemented prior to production. Since the macromodels do not incorporate worst case performance characteristics, the data sheet specifications should be used as a predictor of the range of operation that would be expected. Comlinear offers a selection of evaluation boards to assist in the engineering evaluation of any of the parts discussed in these macromodels.

The macromodels use internal references to a global ground node. Ground currents in simulation are simply a modeling artifact since none of the physical op amps use a separate ground reference.

An example Pspice simulation file using the CLC400 to test the small signal frequency response at a gain of +2 is shown below. Comparing the results of the simulation, in Figure 2, to the data sheet typical plots shows excellent correlation.

PRODUCT HIGHLIGHTS

CLC400
FAST SETTLING, WIDEBAND LOW-GAIN MONOLITHIC OP AMP
- -3dB bandwidth of 200MHz ($A_v = +2$)
- 0.05% settling in 12ns
- low power, 150mW
- low distortion, -65dBc @ 10MHz
- rise and fall times of 1.6ns
- input offset voltage adjustment

CLC401
FAST SETTLING, HIGH-GAIN MONOLITHIC OP AMP
- -3dB bandwidth of 150MHz
- 0.1% settling in 10ns
- low power (150mW)
- ±7 to ±50 gain

CLC402
LOW-GAIN OP AMP WITH FAST 14-BIT SETTLING
- 0.0025% settling in 25ns (32ns max.)
- 0.5mV input offset voltage, 3μV/°C drift
- ±1 to ±8 closed-loop gain range
- low power (150mW)
- 0.01%/0.05° differential gain/phase

CLC404
HIGH-SLEW RATE WIDEBAND MONOLITHIC OP AMP
- 165MHz large signal bandwidth (5Vpp)
- 2600 V/μs slew rate
- low distortion, -53dBc @ 20MHz
- 0.07% differential gain, 0.03° differential phase

CLC406
WIDEBAND, LOW POWER MONOLITHIC OP AMP
- 160MHz small signal bandwidth ($A_v = +6$)
- 50mW power (±5V supplies)
- 0.02%/0.02° differential gain/phase
- 12ns settling to 0.05%
- 1500V/μs slew rate
- 2.2ns rise and fall time (2Vpp)
CLC409
VERY WIDEBAND, LOW-DISTORTION MONOLITHIC OP AMP
• 350 MHz small signal bandwidth @ \( A_v = +2 \)
• -65/-72dBc 2nd/3rd harmonics (20MHz)
• low noise
• 8ns settling to 0.1%
• 1200 V/\mu s slew rate

CLC410
FAST SETTLING, VIDEO OP AMP WITH DISABLE.
• -3dB bandwidth of 200MHz (\( A_v = +2 \))
• 0.05% settling in 12ns
• low power, 160mW(40mW disabled)
• low distortion, -65dBc @ 10MHz
• fast disable (200ns)
• low differential gain/phase: 0.01%/0.01°
• input offset voltage adjustment

CLC414
QUAD, LOW-POWER MONOLITHIC OP AMP
• 90MHz small signal bandwidth
• 2mA quiescent supply current per amplifier
• 70dB channel isolation @ 5MHz
• 3.3ns rise and fall time (2Vpp)

CLC415
QUAD, WIDE-BANDWIDTH MONOLITHIC OP AMP
• 160MHz small signal bandwidth
• 5mA quiescent supply current per amplifier
• 70dB channel isolation @ 5MHz
• 0.03%/0.03° differential gain/phase

CLC420A
HIGH-SPEED UNITY GAIN VOLTAGE FEEDBACK
• 300MHz small signal bandwidth (\( A_v = +1 \))
• 1100 v/\mu s slew rate
• 0.01% settling in 18ns
• 2pA \(/\mu \text{Hz} \) input current noise
• 4.2 nV/\sqrt{\text{Hz}} input noise voltage

CLC425
ULTRA LOW NOISE WIDEBAND OP AMP
• 1.7GHz gain-bandwidth product
• 1.05nV/\sqrt{\text{Hz}} input noise voltage
• 1.6pA/\sqrt{\text{Hz}} input current noise
• 100\mu V input offset voltage, 2\mu V/°C drift
• 100dB CMRR, 95dB PSRR
• 350V/\mu s slew rate
• 15mA to 5mA adjustable supply current
• gain range \( \pm 10 \) to \( \pm 1000 \text{V/V} \)

CLC430
LOW-GAIN OP AMP WITH DISABLE
• 55MHz small signal bandwidth (4Vpp) (\( A_v = +2 \))
• 2000 V/\mu s slew rate
• \( \pm 5 \text{V} \) to \( \pm 15 \text{V} \) supplies
• 100ns disable to high-impedance output
• 0.05%/0.05° differential gain/phase
• high common mode input voltage

CLC501
HIGH-GAIN, OUTPUT-LIMITING AMPLIFIER
• 110MHz small signal bandwidth (\( A_v = +20 \))
• bipolar output limiting (\( V_{\text{high}} \) and \( V_{\text{low}} \))
• 1ns recovery from clamping/overdrive
• 0.05% settling in 12ns

CLC502
CLAMPING, LOW-GAIN OP AMP WITH FAST 14-BIT SETTLING
• output clamping with fast recovery
• 0.0025% settling in 25ns (32ns max.)
• low power (170mW)
• low distortion, -50dBc at 20MHz

CLC505
WIDEBAND ADJUSTABLE SUPPLY CURRENT MONOLITHIC OPAMP
• specified operation at 1mA, 3.3mA, and 9mA
• 3.4mA \( I_{\text{cc}} \) provides 100MHz bandwidth (\( A_v = +6 \))
• 0.04%/0.06° differential gain/phase at \( I_{\text{cc}} = 3.4 \text{mA} \)

CLC520
AMPLIFIER WITH VOLTAGE CONTROLLED GAIN, AGC-Amp
• 160MHz, -3dB bandwidth
• 2000 V/\mu s slew rate
• 0.04% signal nonlinearity at 4Vpp output
• -43dB feedthrough at 30MHz
• user adjustable gain range
• differential voltage input and single-ended voltage output

In an effort to better serve our customers' high performance, high speed, custom needs, Comlinear is offering the monolithic products in die form. Both the ALC and AMC versions are 100% probe tested to $+25°C$ data sheet electricals and 100% visually inspected. In addition, the AMC version includes element evaluation per method 5008 of MIL-STD-883.

**PHYSICAL CHARACTERISTICS**

- **Metalization:** Top – Gold, $1 \mu$m min. thickness (Bond Pads); Back – Gold
- **Passivation:** SiON, $0.7 \mu$m min.
- **Die Thickness:** 14 mils, $\pm$ 2 mils
- **Die Size:** See applicable data sheet
- **Bond Pad:** 4 mils $\times$ 4 mils min.

**ELECTRICAL CONNECTIONS**

The back side of the die is internally connected to $-V_{OC}$. It is not necessary to electrically connect the back side to the minus supply.

**PROCESS FLOWS**

**ALC DICE PROCESSING FLOWCHART**

1. 100% DC Probe to $+25°C$ Data Sheet Electricals
2. Wafer Saw and DI Water Rinse
3. Wafer Inspection
4. Wafer Lot Qualification
5. Die Sort Into Waffle Packs
6. 100% Die Visual Inspection to M2010 MIL-STD-883
7. QA Sample Visual Inspection and Document Review
8. Seal in Waffle Pack
9. Stock (storage in Dry $N_2$)

**AMC DICE PROCESSING FLOWCHART**

1. 100% DC Probe to $+25°C$ Data Sheet Electricals
2. Wafer Saw and DI Water Rinse
3. Wafer Inspection
4. Element Evaluation MIL-H-38534
   1. Electrical Test per Device SCD
      DC at $-55°C$, $+25°C$, $+125°C$
   2. Wire Bond Evaluation
5. Die Sort Into Waffle Packs
6. 100% Die Visual Inspection to M2010 MIL-STD-883
7. QA Sample Visual Inspection and Document Review
8. Seal in Waffle Pack
9. Stock (storage in Dry $N_2$)

**VISUAL INSPECTION**

All wafers are visually inspected per the requirements outlined in MIL-STD-883, method 2010, Level B.

**TRACEABILITY**

All devices are traceable back to the wafer lot. All documentation relating to each wafer lot will be maintained for a minimum of three years.

**PACKAGING**

All dice are packaged in anti-static waffle pack (10 per pack minimum), face-up oriented for automatic assembly. All dice are considered static sensitive per MIL-M-38510 and should be handled as such. For class ratings see Section 13.

**ORDERING INFORMATION**

See Section 15 or contact factory.
The following product accessories, for use in evaluation of Comlinear products, are available by contacting either your area representative, distributor, or Comlinear directly.

Evaluation Boards

To aid in the evaluation of the CLC103 and CLC203 operational amplifiers, Comlinear has created evaluation PC boards: P/N 730005 is for inverting gain applications and P/N 730006 is for non-inverting gain applications. Both boards will accommodate either the CLC103 or the CLC203.

Note to CLC203 Users

The CLC203's superior input offset voltage and settling characteristics allow the composite amplifier (the LF356 and associated circuitry) to be omitted.

Evaluation Board

To aid in the evaluation of the CLC104 amplifier, Comlinear has created an evaluation PC board: P/N 730007. The PC board schematic, layout, and component placement guide are shown below. Other application information is presented in the CLC104 data sheet.

Printed Circuit Layout and Supply Bypassing

As with any high-frequency device, a good PCB layout is required for optimum performance. This is especially important for a device as fast as the CLC110, which has a typical bandwidth of 730MHz.

To minimize capacitive feedthrough, the pins not connected internally (pins 2, 3, 6, and 7) should be connected to the ground plane. Input and output traces should be laid out as transmission lines with the appropriate termination resistors very near the CLC110. On a 0.065 inch epoxy PCB material, a 50Ω transmission line (commonly called stripline) can be constructed by using a trace width of 0.1" over a complete ground plane.

Figure 1 shows recommended power supply bypassing. The ferrite beads are optional and are recommended only where additional isolation is needed from high-frequency (>400MHz) resonances of the power supply.

Parasitic or load capacitance directly on the output of the CLC110 will introduce additional phase shift in the device, which can lead to decreased phase margin and frequency response peaking. A small series resistor before the capacitance effectively decouples this effect. The graphs on the CLC110 data sheet illustrate the required resistor value and the resulting performance vs. capacitance.

Precision buffed resistors (PRP8351 series from Precision Resistive Products), which have low parasitic reactances, were used to develop the data sheet specifications. Precision carbon composition resistors or standard spirally-trimmed RN55D metal film resistors will work, though they will cause a degradation of AC performance due to their reactive nature at high frequencies.

Evaluation Board

An evaluation board, part number 730012, is available to assist in the evaluation of the CLC110. It may also be used as a guide in developing a printed circuit layout. Figure 1 shows the board’s schematic; Figures 2 through 4 show the board layout.

Evaluation Board Parts List:
- \( R_{in} \) select for desired input impedance
- \( R_{out} \) select for desired output impedance
- \( C_1, C_2 \) 0.1µF ceramic radial lead
- \( C_3, C_4 \) 6.8µF (Sprague 150D series)
- \( L_1, L_2 \) ferrite beads (optional) (Ferroxcube #VK 200 19/4B)
- Hardware (optional)
- Sockets Cambion flush-mount connector jacks
- SMA Connectors (female)
  - Amphenol 901-144 (straight)
  - Amphenol 901-143 (angled)
Figure 3: Solder side (bottom) as viewed from component side (top)

Figure 4: Component side (top) showing extensive ground plane
The 730023 is an evaluation board designed to aid in the evaluation and characterization of the CLC114 and CLC115 closed-loop quad buffers. The CLC114 is intended for use in applications requiring lower power operation while the CLC115 is intended for use in systems requiring wider bandwidth and higher output drive capability. Both of these quads offer four unity gain buffers in one 14-pin package. The individual data sheets provide more detailed information on applications and specifications.

The 730023 evaluation board allows for the construction of a number of different circuits utilizing both the CLC114 and the CLC115. Two of the four channels on the board are arranged for the evaluation of signal buffering in a 50Ω environment while two other channels integrate on-board, user-selected, RC active filters. Each type of filter, low pass or bandpass, can be implemented by selecting the appropriate RC component. The filters are designed to use all four of the buffers configured in series: an input buffer, one or two cascaded active filter stages and an output buffer.

The complete schematic of the 730023 evaluation board, showing all component locations, is shown in Figure 3. The parallel resistor/capacitor locations are intended for use with either a resistor or a capacitor with the choice of component depending upon the type of filter. Figure 4 shows the component placement for a cascaded bandpass filter and Figure 5 shows the component placement for the cascaded low pass filter. Each of the two low pass filter sections can be configured as either a second or a third order filter. Configuration of the third order filter requires the placement of additional components. Channel 1 requires R1, C1 and channel 4 requires R5, C5. It will be necessary to cut the 50Ω strip line from the input of channel 3 (pin 5) in order to evaluate the active filter circuit. Separate evaluation of the buffer circuits requires a 50Ω resistor to be placed at the input of channels 1 and 4 (R4 and R9) to insure stability of the unused buffers.

Low Pass Filter Design with the 730023 Evaluation Board

Figure 5 shows the schematic for a low pass filter. The two filter sections may be configured as either a second or a third order filter and therefore, configured in series, provide for a fourth or fifth order low pass filter.

Low Pass Filter Design Equations

It is a common practice in filter design to begin with the synthesis of a filter normalized in frequency and impedance. This method simplifies the derivation of design equations and allows for the convenient calculation of component values. Circuit resistors are normalized to 1Ω and resonant, or cut-off frequencies, are normalized to 1 rad/sec [3]. Now, the design effort is reduced to the calculation of capacitor values in an RC active filter. For simplicity, the filter design equations below use the component designations of channel 1, shown in Figure 5.

Second-Order Filter

Using \( R_2, R_3 = 1Ω \) (\( R_1 = 0, C_1 = 0 \) for second order), the normalized transfer function is

\[
H(s) = \frac{1}{C_3 C_5 s^2 + 2C_3 s + 1}
\]

The roots of this transfer function are a complex pole-pair at \( s = \alpha \pm j\beta \).

\[
H(s) = \frac{1}{\alpha^2 + \beta^2 + 2\alpha s + \frac{s^2}{\alpha^2 + \beta^2}}
\]

equating coefficients in these two equations for the two capacitors yields

\[
C_5 = \frac{1}{\alpha}, \quad C_3 = \frac{\alpha}{\alpha^2 + \beta^2}
\]

The pole locations (values for \( \alpha \) and \( \beta \)) for all filter types (Butterworth, Bessel, Chebyshev etc.) can be found in the references listed at the end of this application note.

Third-Order Filter

Using \( R_1, R_2, R_3 = 1Ω \), the normalized transfer function is

\[
H(s) = \frac{1}{A s^3 + B s^2 + C s + 1}
\]

where

\[
A = C_1 C_4 C_5; \quad B = 2C_4 (C_2 + C_5); \quad C = C_1 + 3C_4
\]

Solving for the capacitor values in terms of the pole locations is cumbersome. As a practical matter, the capacitor values have been tabulated [2] for this filter topology. The design of an \( n^e \) order filter is done by looking up capacitor values for a filter normalized to a \(-3dB\) frequency of \( 1 \) rad/sec.

Once the normalized capacitor values have been found, the actual component values are found by scaling for frequency and impedance. The normalized capacitor values are frequency scaled by dividing them by the desired cut-off frequency \( \omega_c \) and the impedance scaling is then performed by dividing the frequency scaled capacitor values by a resistor of value \( R \). This resistor value is chosen such that impedance scaling produces reasonable capacitor values. All resistances have been assumed equal for a particular filter section. The resistors (normalized to 1Ω) are then impedance...
scaled by multiplying by the impedance scaling factor \( R \). The following equation summarizes these two steps for calculating actual capacitor values.

\[
C = \frac{C_{\text{normalized}}}{2\pi f_c R}
\]

**Design Example. Fifth-Order Bessel Low Pass, \( f_c = 1 \text{MHz} \).**

A fifth-order Bessel (maximally flat delay) low pass filter can be built from a cascade of a third and a second-order filter section. A fifth-order polynomial must first be factored into second and third order polynomials (whose product is the desired fifth-order Bessel polynomial). The cascade of a second and a third-order Bessel polynomial does not yield a fifth-order Bessel polynomial. For a fifth-order circuit, the following normalized capacitor values are found [2].

third-order section: \( C_5 = 1.010 \text{F}; C_4 = 0.3095 \text{F}; C_3 = 0.8712 \text{F} \)

second-order section: \( C_5 = 1.041 \text{F}; C_4 = 0.3100 \text{F} \)

Scaling for frequency and impedance, the calculated component values are as follows:

third-order section:
\[
R = 2.37k\Omega; C_5 = 68pF; C_4 = 20.8pF; C_3 = 58.8pF
\]

second-order section:
\[
R = 1.82k\Omega; C_5 = 91pF; C_4 = 27.1pF
\]

Due to buffer input capacitance, \( C_1 \) and \( C_4 \) were slightly decreased in value. A circuit was built according to Figure 5 with these component values:

\[
R_{\text{int}1}, R_{\text{eq}2}, R_{11} = 500\Omega; R_1, R_2, R_3 = 2.37k\Omega; R_7, R_8 = 1.82k\Omega
\]

\[
C_{11}, C_{14} = 6.8\mu F; C_{12}, C_{13} = 0.1\mu F; C_1 = 56pF, C_4 = 18pF; C_5 = 68pF; C_9 = 24pF, C_{10} = 91pF; R_6, C_6 = 0
\]

In the passband, the group delay (\( \tau \)) for a fifth-order Bessel lowpass filter [1] is

\[
\tau = \frac{2.4}{2\pi f_c \sec} \quad \text{for} \quad f_c = 1 \text{MHz}, \quad \tau = 382\text{nsec}
\]

Figure 1 shows the frequency response of the magnitude, phase and group delay. The group delay can be approximated from the phase from the equation

\[
\tau = \frac{\Delta \phi \text{(degrees)}}{360^\circ / (\Delta f)}
\]

where \( \Delta \) is the delay aperture, \( \Delta \phi \) is the phase change over the delay aperture. In this filter, the group delay was constant within 3\% to 1.3MHz, using a delay aperture of 25kHz.

Comlinear CLC2XX Series Evaluation Boards
Part Numbers 730008, 730009

Evaluation Board for CLC200, 201, 205, 206, 207, 220, 221, 231, and 232

Description
Comlinear part numbers 730008 (inverting) and 730009 (non-inverting) are evaluation boards designed to help design engineers evaluate and use the CLC2XX Series op amps. In addition, the boards can serve as a guide for engineers who are developing printed circuit layouts for op amps.

Part number 730008 is designed for inverting gains, and part number 730009 is designed for non-inverting gains. Each is discussed individually.

Part Number 730008 – Inverting Gains

Note to CLC231/232 Users: Cut traces between pins 11 and 8 on bottom at board and add a 250 Ω resistor between pins 5 and 11 (on bottom).
Part Number 730009 – Non-Inverting Gains

Evaluation Boards
To aid in the evaluation of CLC300 operational amplifiers, Comlinear has created an evaluation PC board, P/N 730010. This board is designed for use in either inverting or non-inverting configurations, as Figures 1 through 4 illustrate.

Operational Hints
A few suggestions will help to maximize the usefulness of this board:

Optimum performance is obtained without the use of sockets. However, if sockets are necessary, flush mount connector jacks from Cambion (P/N 450-2598-01-03-00) are recommended. To minimize capacitance between pins, jacks should be used only where contact to the CLC300 must be made (pins 6, 8, 11, 12, 13, 16, 24).

In an effort to simplify this layout, $-V_{cc}$ has been routed through pin 10 of the CLC300. This routing, however, causes approximately 0.2dB of frequency-response peaking. This peaking can be eliminated by floating pin 10 either by cutting that pin away from the package or by rerouting the $-V_{cc}$ trace.

The board is shaped to fit the Modpak case 7042.

General Layout Considerations
To assure optimum performance, the user should follow good layout practices which minimize the unwanted coupling of signals between nodes. Avoid wire-wrap type PC boards and methods.

During PC board layout, keep all traces short and direct. The resistive bodies of $R_1$ and $R_g$ should be as close as possible to pin 8 to minimize capacitance at that point. For the same reason, remove ground plane from the vicinity of pins 6, 7 and 8. In other areas, use as much ground plane as possible on one side of the PC board. It is especially important to provide a ground return path for current from the load resistor to the power supply bypass capacitors. Ceramic capacitors of .01 to .1μF should be close to pins 13 and 16. Larger tantalum capacitors should also be placed within one inch of these pins.

To prevent signal distortion caused by reflections from impedance mismatches, use terminated microstrip or coaxial cable when the signal must traverse more than a few inches. Since the PC board forms such an important part of the circuit, much time can be saved if prototype boards of any high-frequency sections are built and tested early in the design phase.

Figure 6: Solder (bottom) side as viewed from component (top) side
DESCRIPTION
The 730013 (Rev.C) is an evaluation board configured to accommodate most of Comlinear's 8-pin monolithic amplifier products in a standard through-hole DIP. A companion board, the 730027 (Rev. C) is also available for easy evaluation of the 8-pin plastic SOIC (surface mount) packages (AJE suffix). These boards are set up to yield a non-inverting gain determined by the $R_f$ and $R_g$ resistors. Additionally, typical op amp topologies, such as inverting and differential amplification, can be easily implemented by slight modifications to the board. With the introduction of the Rev. C board (July, 1991) the following Comlinear amplifier products may be evaluated using this board. (Unless specifically stated otherwise, all of these are current feedback amplifiers using +/-5V supplies.)

**CLC400** → A wideband amplifier optimized for low gain operation

**CLC401** → A wideband amplifier optimized for high gain operation

**CLC402** → A high accuracy (.0025%) amplifier for low gain operation

**CLC404** → A wideband, high slew rate amplifier for intermediate gains

**CLC406** → An intermediate gain amplifier with low quiescent power

**CLC409** → A low gain, wideband amplifier with low harmonic distortion

**CLC410** → A low gain amplifier with a shutdown capability

**CLC411** → A wideband, low gain amplifier using +/-15V power supplies

**CLC420** → A unity gain stable, wideband, voltage feedback amplifier

**CLC422** → A very high gain-bandwidth product voltage feedback amplifier

**CLC425** → A very low-noise, wideband, voltage feedback amplifier.

CLC430 → An intermediate performance amplifier using +/-15V supplies

CLC501 → A high gain amplifier with output clamping capability

CLC502 → A low gain amplifier with output clamping and .0025% settling

CLC505 → An intermediate gain amplifier with adjustable supply current

Please refer to the detailed data sheets on each of these parts for a full description of their performance capabilities.

The high frequency signal path required by each of these parts is identical. Hence, the AC portion of the layout can be used as a guide to good high frequency layout for any of these amplifiers. See application note OA-15 for additional layout suggestions. For good high frequency performance, close power supply de-coupling to a low inductance ground plane is required. Capacitors C1 through C4 provide this for any of the parts built up on this board.

Since all of the above listed parts are op amps, their non-inverting input impedance is typically quite high, while the output impedance is very low. Hence, the board input/output impedance is set for all of these parts using the $R_{in}$ and $R_{out}$ resistors.

The following diagrams show a typical circuit implementation for each of the devices accommodated by this board. The circuit and the component values shown for each part correspond to the non-inverting test configuration used to generate the specifications shown on each part's data sheet. Please refer to the specific data sheets for a discussion of any external components shown on the following schematics but unique to the use of that part.

The CLC400 is a wideband current feedback op amp optimized for low gains.

**Recommended Values:**

- $R_{in} = R_{out} = 50\Omega$
- $R_f = R_g = 250\Omega$ ($A_v = +2$)
- $C_1 = C_2 = .1\mu F$ ceramic
- $C_3 = C_4 = 6.8\mu F$ tantalum
- $R_5 = 20k\Omega$ pot (optional input offset voltage null)
- $C_7 = .01\mu F$ ceramic (should be used for best fine scale settling even if $R_5$ not used)

**Components not used:**

- C5, C6, C8
- R1, R2, R3, R4, R6, R7, R8

14 - 17
CLC401 is a wideband current feedback op amp optimized for high gains.

**Recommended Values:**
- $R_{in} = R_{out} = 50\Omega$
- $R_f = 1.5k\Omega$
- $R_g = 78.7\Omega$ ($A_v = +20$)
- $C1 = C2 = .1\mu F$ ceramic
- $C3 = C4 = 6.8\mu F$ tantalum

**Components not used:**
- C5, C6, C7, C8
- R1 → R8

The CLC402 is a wideband current feedback op amp optimized for low gains, offering extremely fast settling to .0025% accuracy.

**Recommended Values:**
- $R_{in} = R_{out} = 50\Omega$
- $R_f = R_g = 250\Omega$ ($A_v = +2$)
- $C1 = C2 = .1\mu F$ ceramic
- $C3 = C4 = 6.8\mu F$ tantalum
- $R7 = R8 = 10\Omega$ (optional series supply resistors - component side supply traces shorting R7 & R8 should be cut to use these resistors.)

**Components not used:**
- C5, C6, C7, C8
- R1 → R6

The CLC404 is a wideband op amp optimized for intermediate gain with extremely broad full power bandwidth.

**Recommended Values:**
- $R_{in} = R_{out} = 50\Omega$
- $R_f = 500\Omega$
- $R_g = 100\Omega$ ($A_v = +6$)
- $C1 = C2 = .1\mu F$ ceramic
- $C3 = C4 = 6.8\mu F$ tantalum

**Components not used:**
- C5, C6, C7, C8
- R1 → R8
The CLC406 is an intermediate performance, low quiescent power op amp optimized for midrange gains (+/-1 to +/-10)

**Recommended Values:**
- $R_{in} = R_{out} = 50\Omega$
- $R_f = 500\Omega$
- $R_g = 100\Omega$ ($A_v = +6$)
- $C_1 = C_2 = 0.1\mu F$ ceramic
- $C_3 = C_4 = 6.8\mu F$ tantalum

**Components not used:**
- $C_5, C_6, C_7, C_8$
- $R_1 \to R_8$

The CLC409 is a very wideband op amp optimized for low gains and offering exceptionally low harmonic distortions.

**Recommended Values:**
- $R_{in} = R_{out} = 50\Omega$
- $R_f = R_g = 2500\Omega$ ($A_v = +2$)
- $C_1 = C_2 = 0.1\mu F$ ceramic
- $C_3 = C_4 = 6.8\mu F$ tantalum
- $C_8 = 0.01\mu F$ (optional supply to supply de-coupling for reduced distortion)

**Components not used:**
- $C_5, C_6, C_7$
- $R_1 \to R_6$

CLC410 is a wideband op amp optimized for low gains (very similar to the CLC400) with an output disable capability.

**Recommended Values:**
- $R_{in} = R_{out} = 50\Omega$
- $R_f = R_g = 2500\Omega$ ($A_v = +2$)
- $C_1 = C_2 = 0.1\mu F$ ceramic
- $C_3 = C_4 = 6.8\mu F$ tantalum
- $R_5 = 20k\Omega$ pot (optional input offset voltage null)
- $C_7 = 0.01\mu F$ ceramic (should be used for best fine scale setting even if $R_5$ not used)
- $R_3 = 0-1k\Omega$ (open collector disable control.
Note: trace connecting $R_3$ to $+V_{cc}$ must be cut; $R_3$ connects to disable logic.)

**Components not used:**
- $C_5, C_6, C_8$
- $R_1, R_2, R_4, R_6, R_7, R_8$
The CLC411 is a wideband op amp optimized for low gains and using +/-15V power supplies.

**Recommended Values:**
- $R_{in} = R_{out} = 50\Omega$
- $R_f = R_g = 500\Omega$ ($A_v = +2$)
- $C1 = C2 = .1\mu F$ ceramic
- $C3 = C4 = 6.8\mu F$ tantalum
- $C6 = C7 = .01\mu F$ ceramic
- $R3 = 0-1k\Omega$ (open collector disable control. Note: trace connecting R3 to $+V_{cc}$ must be cut; R3 connects to disable logic.)

**Components not used:**
- C5, C8
- R1, R2, R4, R5, R6, R7, R8

The CLC420 is a wideband, unity gain stable, voltage feedback op amp with very low quiescent power dissipation.

**Recommended Values:**
- $R_{in} = R_{out} = 50\Omega$
- $R_f = R_g = 500\Omega$ ($A_v = +2$)
- $C1 = C2 = .1\mu F$ ceramic
- $C3 = C4 = 6.8\mu F$ tantalum

**Components not used:**
- C5, C6, C7, C8
- R1 → R8

The CLC422 is a very high gain-bandwidth (8 GHz) voltage feedback op amp optimized for high gains.

**Recommended Values:**
- $R_{in} = R_{out} = 50\Omega$
- $R_f = 1.5k\Omega$
- $R_g = 38.3\Omega$ ($A_v = +40$)
- $C1 = C2 = .1\mu F$ ceramic
- $C3 = C4 = 6.8\mu F$ tantalum

**Components not used:**
- C5, C6, C7, C8
- R1 → R8
The CLC425 is a very low noise, wideband, voltage feedback op amp with an adjustable supply current feature.

**Recommended Values:**
- $R_{in} = R_{out} = 50\Omega$
- $R_{f} = 500\Omega$
- $R_{g} = 26\Omega (A_{v} = +20)$
- $C_{1} = C_{2} = .1\mu F$
- $C_{3} = C_{4} = 6.8\mu F$ tantalum
- $R_{6}$ = (sets supply current—see data sheet)
- $R_{7} = R_{8} = 10\Omega$ (optional series supply resistors—see CLC425 discussion)

**Components not used:**
- $R_{1}, R_{2}, R_{3}, R_{4}, R_{5}$
- $C_{5}, C_{6}, C_{7}, C_{8}$

The CLC430 is an intermediate performance op amp using +/-15V supplies, optimized for low gains, and offering a disable feature.

**Recommended Values:**
- $R_{in} = R_{out} = 50\Omega$
- $R_{f} = R_{g} = 750\Omega (A_{v} = +2)$
- $C_{1} = C_{2} = .1\mu F$ ceramic
- $C_{3} = C_{4} = 6.8\mu F$ tantalum
- $R_{3}$ = 0-1kΩ (open collector disable control. Note: trace connecting $R_{3}$ to +Vcc must be cut; $R_{3}$ connects to disable logic.)

**Components not used:**
- $C_{5}, C_{6}, C_{7}, C_{8}$
- $R_{1}, R_{2}, R_{4}, R_{5}, R_{6}, R_{7}, R_{8}$

The CLC501 is a wideband op amp optimized for high gains and offering an extremely fast output voltage clamping capability.

**Recommended Values:**
- $R_{in} = R_{out} = 50\Omega$
- $R_{f} = 1.5k\Omega$
- $R_{g} = 48.7\Omega (A_{v} = +32)$
- $C_{1} = C_{2} = .1\mu F$ ceramic
- $C_{3} = C_{4} = 6.8\mu F$ tantalum
- $R_{1} = R_{2} = 825\Omega$
- $R_{3} = R_{4} = 1.27k\Omega$ (clamps at +/-3V)
- $C_{5} = C_{6} = .01\mu F$ ceramic (optional clamp de-coupling)

**Components not used:**
- $C_{7}, C_{8}$
- $R_{5} \rightarrow R_{8}$
The CLC502 is a wideband op amp optimized for low gains with exceptional settling to .0025% accuracy and a high speed output clamping capability.

**Recommended Values:**
- $R_{\text{in}} = R_{\text{out}} = 50\Omega$
- $R_f = R_g = 250\Omega$ ($A_v = +2$)
- $C_1 = C_2 = .1\mu F$ ceramic
- $C_3 = C_4 = 6.8\mu F$ tantalum
- $R_1 = R_2 = 825\Omega$
- $R_3 = R_4 = 1.27k\Omega$ (clamps at +/-3V)
- $C_5 = C_6 = .01\mu F$ ceramic (optional clamp de-coupling)
- $R_7 = R_8 = 10\Omega$ (optional series supply resistors - see CLC402 discussion)

**Components not used:**
- $R_5, R_6$

The CLC505 is a wideband op amp optimized for intermediate gains and offering an adjustable supply current feature.

**Recommended Values:**
- $R_{\text{in}} = 50\Omega$
- $R_{\text{out}} = (\text{see data sheet})$
- $R_f = 1k\Omega$
- $R_g = 200\Omega$ ($A_v = +6$)
- $C_1 = C_2 = .1\mu F$ ceramic
- $C_3 = C_4 = 6.8\mu F$ tantalum
- $C_5 = 100pF$ ceramic
- $R_6 = (\text{sets supply current - see data sheet})$

**Components not used:**
- $C_6, C_7, C_8$
- $R_1, R_2, R_3, R_4, R_5, R_7, R_8$

Input and Output connectors are SMA board mount type - such as
- Amphenol 901-144 (straight)
- Amphenol 901-143 (angled)

The amplifier may be socketed using Cambion flush mount connector jacks (P/N 450-2598).

Resistor types - For best AC performance, low reactance precision buffed resistors from Precision Resistive Products (PRP8351 series) should be used. Precision carbon composition resistors will also yield excellent results while standard spirally trimmed RN55D precision metal film resistors will also work with a slight decrease in AC performance.
The 730024 is an evaluation board designed to facilitate the characterization of the CLC414 and CLC415 quad current-feedback amplifiers. The CLC414 is designed for low power applications, while the CLC415 provides wider bandwidth and higher output current drive. Both the CLC414 and CLC415 offer four high-speed amplifiers in one 14-pin package. Please refer to the individual data sheets for more detailed information on the specifications and application of these devices.

The 730024 evaluation board configures the CLC414 and CLC415 as non-inverting amplifiers in a 50Ω environment. Inverting gain and differential amplifier circuits can be built with slight modifications to the board. It also serves as a layout guide for engineers developing their own printed circuit boards. Particular attention should be paid to the use of a ground plane and power supply bypassing. Figure 1 shows the layout of the board. Figure 2 is the complete board schematic.

**Recommended Component Values**

RIN1, RIN2, RIN3, RIN4 = 50Ω

ROUT1, ROUT2, ROUT3, ROUT4 = 50Ω

RF1, RF2, RF3, RF4 = 500Ω

RG1, RG2, RG3, RG4 = 100Ω

C1, C2 = 0.1μF ceramic

C3, C4 = 6.8μF tantalum

---

**Figure 1:** Board Layout and Component Placement

**Figure 2:** Board Schematic
The #730029, Rev. B (through-hole) evaluation board provides an easy means of testing the operation and performance of both the CLC520 and the CLC522 in their 14-pin DIP packages. **Note, this board obsoletes an earlier CLC520 evaluation board - part #730021.** A similar board, #730033, Rev. B, (SOIC) accommodates the CLC520 and CLC522 surface mount versions. Please refer to the CLC520 and the CLC522 data sheets for complete performance information.

I. Basic Operation

Figure 1 shows the complete evaluation circuit implemented on this board. The primary connections are shown with solid lines, while several optional circuit connections are shown with dashed lines.

The CLC520 and the CLC522 have the same pin definitions with the only exception of an additional +Vcc connection on pin 13 of the CLC522, whereas pin 13 is a no-connect on the CLC520. The evaluation board hard-wires pin 13 and pin 14 together, applying +Vcc to both pins allowing the board to accommodate both devices. The key operational differences between the CLC520 and the CLC522 are found with the gain-adjust input (Vg; pin 2). The gain-adjust input voltage range of the CLC520 is 0-2V while that for the CLC522 is ±1.0V. Also the gain-adjust input resistance (pin 2 to ground) is typically 750kΩ for the CLC520 and typically 100kΩ for the CLC522. One wiring difference should be noted, the ground connection from pin 9 (R11 on the evaluation board) of the output amplifier's non-inverting input should be a very low inductance short to ground for the CLC520 and 20Ω for the CLC522.

II. Basic CLC520 Connection

Figure 2 represents the simplest board configuration for the CLC520. The specific resistor values depicted here configure the CLC520 with a maximum gain of +10V/V; this is the condition used to specify the part in its data sheet.

![Figure 2: Basic CLC520 connection](image)

The circuit of Figure 2 implements a non-inverting variable-gain amplifier with a 50Ω input impedance (R1), a 50Ω output impedance (R6), and a maximum gain of +10V/V (1.85-(R7/R3)). Recognizing the combination of the 50Ω series output resistor and the 50Ω load results in a voltage divider, the gain to this matched load is one half of the maximum device gain setting, i.e. +5 (14dB). The gain-adjust input has a 0-2V range with Vg > 2.0V yielding the maximum gain while Vg = 0V yields the maximum signal attenuation. Note, the CLC520’s parallel combination of R4 (53.6Ω) and its internal 750Ω resistor to ground on pin 2 results in a 50Ω input impedance for Vg. The inverting input (In-) is ground-referenced through 50Ω while the output amplifier’s non-inverting input is ground-referenced at pin 9. The evaluation board provides a component location at pin 9 (R11) used as a ground connection for the CLC520. This ground connection should be very short from the hole for R11 directly to the top-side ground plane, not a long wire in place of R11. In an application board layout, the CLC520’s pin 9 should be taken directly into a very low-inductance ground plane with as little lead length as possible. This will...
prevent the possibility of a high-frequency resonance (> 400 MHz) in the output amplifier’s input stage from causing any stability or frequency response problems. Earlier discussions of the CLC520 implied that pin 9 could be used to introduce a DC offset into the output amplifier. Due to its limited input voltage range and the need for a broadband low source impedance on pin 9, this method of introducing a DC offset is not recommended. As will be discussed later, an additional signal or DC offset can be more effectively introduced through the inverting input (pin 12).

III. Basic CLC522 Connection

Figure 3 shows the simplest configuration for evaluating the CLC522. The specific resistor values depicted here configure the CLC522 with a maximum gain of +10V/V; this is the condition used to specify the part in its data sheet.

![Figure 3: Basic CLC522 connection](image)

This circuit is nearly identical to that of the CLC520. The only two circuit changes are seen at the gain-adjust input (pin 3), terminated here in 50Ω as opposed to the CLC520’s 53.6Ω (the difference lies in the fact that the CLC522 has a much greater input impedance through pin 2 than the CLC520) and the ground-reference of the output amplifier (pin 9) is taken to ground through a 20Ω resistor (R11). The input gain-adjust voltage range of the CLC522 is ±1V. -1V for minimum gain (maximum attenuation) to +1V for maximum gain set by 1.85·(R7/R3). Again, the ground connection on pin 9 is very critical to the high-frequency stability of the amplifier. In this case the 20Ω resistor acts to stabilize a high frequency (>400 MHz) resonance in the output stage. An optional power-supply decoupling capacitor (C8) is shown with the CLC522 on pin 13 of Figure 1. A 0.01μF capacitor located at C8 can be used to slightly improve the device’s fine scale pulse settling time, however, in most cases this capacitor is not required for evaluation.

IV. Gain Control Input Resistor Options

Two additional resistor locations (R12 & R13) are included on the gain-adjust line. The resistor locations may be used to introduce a DC bias on pin 2. Figure 4 provides an example of how R12 and R13 can be used to fix the CLC520 and the CLC522 at their maximum gains by applying a resistive DC-bias voltage on pin 2 in the absence of an applied Vg input. Note, the CLC520 presents an approximate 750Ω resistance on pin 2 while the CLC522 is typically 100kΩ.

![Figure 4: Setting up for the fixed maximum gain](image)

A related CLC522 application (shown above) reverses the positions of the two resistors, resulting in a negative DC bias on pin 2. This arrangement will place the part into a default maximum-attenuation mode and therefore, in the absence of an applied Vg voltage, isolate the part from signal transmission. Since the resistors used here are relatively large, any DC source for Vg can be used to drive pin 2 to the desired gain-control voltage.

V. Summing Signals and Offsets into the Output Stage

The output amplifier’s inverting node (pin 12) is available to introduce any additional signals or offsets into the output. Since pin 12 is a virtual ground, additional signals may be summed into this node without a substantial impact of the signal current flowing from the adjustable-gain path. Briefly, adding an additional impedance on the inverting input of the output amplifier will result in a slight bandwidth reduction of the output amplifier and an increase in the noise gain for the output amplifier’s non-inverting input noise voltage. Refer to application note OA-13 for a more thorough discussion of current feedback amplifiers in inverting summing applications. Figure 5 shows an example of using the optional components on the board to sum in a high-speed signal with a gain of -2 to the output pin (or -1 to the matched 50Ω load).
Note, R6 can be used in either of two locations on this board. In Figure 5 R6 is positioned as part of the output op amp's inverting input (In2) termination. Alternatively, it can be positioned to pick off the wiper voltage of an offset-adjust pot (R14 Figure 1) which is to be fed into the inverting node of the output amplifier. Figure 6 shows this application where an output offset, independent of the gain adjustment stage, is introduced into the inverting node of the output amplifier.

Adjusting the input and the output stage offsets at the two gain extremes will hold the output DC error at a minimum at these two points in the gain range. If a more limited gain range is anticipated, the adjustments should be made at these operating points. The non-linear DC error introduced by the multiplier core will cause a residual, gain dependent, offset to appear at the output as the gain is swept from minimum to maximum. Also, neither the input nor the output offset adjustments described here will improve temperature drift effects. Please see the CLC522 data sheet for a more complete discussion of DC offset control.

VII. Printed Circuit Board Layout

The CLC520/522 evaluation boards show a careful attention to parasitic effects in the layout. Generally, any parasitic coupling path to an AC ground (this includes both power and ground planes) should be avoided at any of the signal input and output pins. At the same time, a very good, close proximity, ground plane needs to be provided for the power supply de-coupling capacitors. These boards show the ground plane totally opened up around the part, but close enough to provide minimum parasitic inductance for the de-coupling capacitor connections. The ground plane on the evaluation boards is also part of a 50Ω transmission line inductance implemented on the two buffer input and gain adjust traces.

VI. Nulling the Output DC Offset

Both the CLC520 and the CLC522 consist of three major functional sections each of which contributes a DC offset voltage to the output of the device: the differential input buffer, the multiplier core and the output amplifier. The offsets produced by the input buffer and the output amplifier can be nulled with the appropriate external circuitry. It will not be possible to completely null the offset effects of the multiplier core because of its nonlinear nature. As a result, a small nonlinear DC offset voltage gain over the adjustment range will always be present at the output of the device. Figure 7 shows the required external circuitry necessary to add the appropriate nulling offsets at both the input buffer and the output amplifier.
Best frequency response flatness is obtained if there is minimal parasitic capacitance to ground on the output of the two input buffers, pins 4 & 5. The gain setting resistor (R3 on these boards) should be in very close proximity to these pins with short, symmetric, PC board traces connecting to pins 4 & 5. As application note OA-16 describes, this trace symmetry to the gain setting resistor will improve the high frequency CMRR in differential amplifier applications.

All of the I/O pins associated with the output stage amplifier are particularly sensitive to parasitic capacitance to an AC ground. The non-inverting input pin (pin 9) should be tied directly to the ground plane for the CLC520, while a 20Ω resistor to ground (R11) should be used for the CLC522. The output amplifier’s feedback resistor (R7), should also be connected between the output and the inverting input (pins 10 & 12) with minimum trace length and parasitic coupling to any AC ground. And finally, the output pin should be buffered from the load by a resistor, (R8), that is acting as either an impedance matching resistor, for driving a doubly terminated transmission line, or as an isolation resistor, when driving capacitive loads. Please see the amplifier data sheets for the recommended series resistor value vs. capacitive load.

Figures 8 and 9 show the board layouts for these two evaluation boards.

Evaluation Board Parts List - See the device data sheets along with the discussion and examples shown here when selecting component values.

The I/O connector styles are:
- SMA (straight) Amphenol 901-144
- SMA (right-angled) Amphenol 901-143

The device through-holes on the 730029 board are large enough to accommodate flush-mount socket pins if it is desired to socket the part. These should be Cambion P/N 450-2598 or equivalent. It is important not to use a standard 14-pin socket since the relatively long connector distance above the board will severely degrade the AC performance of the CLC520 and CLC522.
The 730028 (Rev. B) evaluation board is designed to aid in the evaluation and characterization of the CLC532, 2:1 analog multiplexer. Designed for very wide dynamic range systems, the CLC532 provides a wideband, unity gain, two-channel multiplexer with exceptional switching speeds. High channel isolation and fast pulse settling, make the CLC532 ideal for 12-bit ADC input-multiplexing applications. The CLC532 data sheet provides more detailed performance and applications information.

Basic Operation
The complete circuit schematic of the 730028 evaluation board, including components for optional circuit configurations, is illustrated in Figure 1. The primary connections are shown with solid lines while the optional input and digital interface connections are shown with dashed lines.

![Figure 1: CLC532 Evaluation Board Schematic](image)

The CHANNEL A and B (pins 2 & 4) analog inputs of the CLC532 are buffered high-impedance pins. The two input termination resistors ($R_{INA}$ & $R_{INB}$) provide impedance matching for the analog sources; a 50Ω environment is assumed. The closed-loop active output of the CLC532 provides a very low output impedance, typically 1.2Ω. For driving 50Ω systems, a 48.7Ω series output resistor ($R_{OUT}$) will provide a close back matched impedance for 50Ω cables.

![Figure 2: Driving Remote A/D Converter Inputs](image)

Figure 2 illustrates the CLC532 evaluation board connections when driving the high-impedance input of a remote A/D converter. Most high quality, high-resolution, A/D converters employ a high-impedance input stage. This allows the CLC532 to operate with relatively high load resistors (>200Ω), greatly improving CLC532 distortion performance. When the CLC532 drives the A/D converter remotely from a separate board, a 48.7Ω series output resistor prior to a 50Ω connecting cable followed by a 450Ω termination resistor at the input of the A/D converter, results in an effective 500Ω load. When driving A/D converter inputs directly, a 500Ω termination load is recommended with no series resistance.

The CLC532 is capable of functioning with ECL, TTL, and CMOS logic families. Logic compatibility is controlled by $D_{REF}$. In normal operation, $D_{REF}$ is left floating and the channel SELECT responds to ECL level signals. For TTL and CMOS level SELECT inputs, $D_{REF}$ should be tied to +5V (the CLC532 $D_{REF}$ input is internally buffered through a 2300Ω resistor). TTL and CMOS operation requires the use of a resistor input network for the channel SELECT. Without the input network, SELECT logic levels above 3V will cause internal junction saturation and slow switching speeds.
The ClC532 evaluation board is labeled for ±5V supplies. Normal ECL logic, and many A/D converters, employ a -5.2V VEE supply rather than the indicated -5.0V supply. Either value is acceptable with negligible impact on performance.

Figure 3: Basic Evaluation Schematic

Figure 3 illustrates the basic ClC532 multiplexer configuration. This configuration terminates both inputs with 50Ω and places a 48.7Ω back-terminating resistor (R_{OUT}) at the output. With D_{REF} left floating (ECL logic levels), the channel SELECT input is terminated with a 50Ω resistor to ground. This configuration assumes a 50Ω signal source provides the channel SELECT input. If standard ECL logic devices are available to drive the channel SELECT input directly, the evaluation board can be configured for standard Thevenin equivalent input terminations. A 50Ω termination resistor to a -2V bias supply can also be used. See Channel SELECT Logic Interfaces section. The overall gain seen at the matched load is 0.5V/V (-6dB). The compensation capacitors (C5 & C6) have been selected for a maximally-flat frequency response.

Compensation Capacitors
The compensation capacitors (C5 & C6) are used to tune the ClC532's frequency response for a given load. Figure 4 provides the compensation capacitor values for a maximally-flat frequency response. For symmetric slew rates, C5 and C6 should be equal. Figure 5 provides the -3dB bandwidth and slew rate vs. compensation capacitor values. The compensation capacitors can be used to limit the ClC532's noise-bandwidth. Given a single-pole frequency response, the noise bandwidth will be approximately \( \frac{1}{(1.57)f_{3dB}} \).

Figure 5: Slew Rate and Bandwidth vs. Compensation

Channel SELECT Logic Interfaces
The ClC532 accepts channel SELECT inputs from a variety of logic families and sources. During evaluation, a signal generator is commonly used to drive the channel SELECT input. Accordingly, the evaluation board has been initially configured with a 50Ω SELECT input termination resistor to ground. When driving channel SELECT with actual ECL, TTL or CMOS logic gates, it will be necessary to add an appropriate input network. The 730028 evaluation board provides the necessary component locations for these networks, and Figure 6 illustrates the recommended TTL and CMOS configurations.
The TTL and CMOS networks limit the maximum voltage swing at the channel SELECT input (pin 7) to less than 3.0V. Exceeding 3.0V will saturate the internal switching logic and cause slower switching speeds. If the input of the TTL or the CMOS networks is left floating, CHANNEL A will be selected. Use of the series resistor (R5) requires the cutting of the channel SELECT input trace below R5. This is easily accomplished on the back side of the evaluation board.

Driving the CLC532 with standard ECL logic gates requires one of the standard ECL terminations at the channel SELECT input. The network of Figure 7 provides a Thevenin equivalent termination of 50Ω to -2V. If a -2V bias supply is available, the standard 50Ω to -2V is certainly acceptable. Allowing the input to this network to float will select CHANNEL B.

**Figure 7: Standard ECL Terminations**

**Signal Input Options**

The CLC532 evaluation board is capable of implementing a switched gain stage by driving CHANNEL B with an attenuated version of the CHANNEL A input signal. Illustrated in Figure 8, this circuit quickly switches between the full amplitude signal at CHANNEL A and the -6dB version of that signal at the input of CHANNEL B. This circuit provides a simple 50Ω termination for the channel SELECT input, although any of the previous circuits are equally acceptable. The series resistor at the input of CHANNEL A (R7) matches its source impedance to that of CHANNEL B (ie. R7=R6||R\text{nB}), generating equal poles from the parasitic input capacitances. This type of source impedance matching will also minimize input bias current induced offset errors.

**Figure 8: Basic Gain Select Configuration**

The switched-gain circuit of Figure 8 should be driven from a low output impedance, wideband, amplifier. Figure 9 uses a CLC406 at a gain of +2V/V to drive both inputs of the CLC532 switched gain circuit. With CHANNEL A selected, the signal at $V_{\text{OUT}}$ will be a 0dB (unity gain) version of the input signal. With CHANNEL B selected, the CLC532 will produce a -6dB (0.5V/V) representation of the input signal at $V_{\text{OUT}}$. Figure 10 shows the signal at $V_{\text{OUT}}$ using a 10MHz analog input signal, with the channel SELECT toggled at 500kHz. This approach can be easily extended to different gain settings.

**Figure 9: CLC406 Driver for the Switched Gain Configuration**
Board Layout Suggestions
The 730028 board has been designed to provide the maximum channel isolation and best fine-scale pulse-settling performance. Channel isolation requires good trace separation between the two inputs, while a ground plane placed between the inputs and the output will serve to isolate the unselected channel from the output.

On the CLC532 evaluation board, the ground connections for the analog input terminating resistors play a strong role in channel isolation performance. The input termination resistor ground connection for CHANNEL B has been placed immediately adjacent to its input SMA connector. The input termination resistor ground connection for CHANNEL A has been placed at right angles to the input trace, and away from the CHANNEL B input. The optimum geometry for input termination resistor ground connections will likely vary from design to design. Some empirical testing may be required.

To achieve high-speed 14-bit settling accuracy, careful attention must be given to ground currents and the electrolytic power supply bypass capacitors. The ground connections of the electrolytic bypass capacitors must have a short and symmetric path to the ground connection of the CLC532 output load. In the case of the 730028 evaluation board, the output SMA connector provides the ground connection for the output load/return currents. Figures 11a,b illustrate the layout for the 730028 evaluation board.

The I/O connectors are SMA (straight) Amphenol 901-144 and SMA (right angled) Amphenol 901-143.

The device thru holes are large enough to accommodate flush mount socket pins if socketing is desired. These should be Cambion P/N 450-2598 or equivalent. Standard DIP sockets are specifically not recommended; the relatively long socket leads will severely degrade the ac performance of the CLC532.
The CLC533 is a high-speed 4:1 multiplexer with buffered inputs and outputs. This monolithic device has been designed using an advanced complimentary bipolar process. The CLC533 evaluation boards (two versions) have been designed as evaluation platforms for CLC533AJP (DIP package) and the CLC533AJE (SOIC package). The part number for the evaluation board supporting the DIP package is 730035, and that for the board supporting the SOIC is 730039.

Figure 1 shows the schematic of the circuit employed on the boards. For a detailed description of device performance please refer to the individual detail data sheet.

The evaluation board has been designed and laid out in a manner to maximize the isolation between the input channels. The steps that have been taken to aid in this include: separation of the inputs as much as is practical, strips of ground plane separating the input traces and the use of termination resistors that have been physically isolated from one another. A strip of ground plane has been placed between the two rows of pins to minimize the interference between the inputs and the outputs of the device.

Digital Interface and Channel SELECT
The CLC533 functions with TTL, CMOS and ECL logic families. The DREF pin determines logic compatibility. With DREF left open (R3 not inserted in board) A0 and A1 will respond to ECL level inputs. R1 and R2 can be used to set input termination networks as required by the driving gate logic family. If DREF is tied to +5V through R3 (approximately 1kΩ), then the select inputs will respond to TTL or CMOS input levels. Note that DREF is internally isolated by a 2300Ω resistor. R1 and R2 should be left open in TTL or CMOS mode.

Input Signal Termination
The analog inputs to the board are brought in through four SMA connectors. The input signals are terminated with RinA, RinB, RinC, and RinD, these resistors should be chosen to match the transmission line impedance of the cable bringing the signals to the board, typically 50Ω or 75Ω.

Power Supplies
The CLC533 operates off of two power supplies, nominally +5V and -5V. Use of an ECL -5.2V supply rather than the -5V supply is allowed/recommended for ECL. The supplies used should be capable of providing 100mA of current each.

Applications Support
Comlinear maintains a staff of applications engineers who are available for design and applications assistance.

730035 DIP version

Figure 5: Bottom layer metal - (top view)  
730035 DIP version
The #730019 PCB from Comlinear is intended to allow the easy evaluation of either the CLC560 or CLC561. These are hybrid DriveR amplifiers primarily intended to drive high signal levels into a matched load with excellent distortion and full power bandwidth capabilities. The CLC560 is optimized for the best pulse settling characteristics, with some sacrifice in full power bandwidth, while the CLC561 is optimized for the highest slew rate, and hence full power bandwidth, with some sacrifice in the long term pulse settling accuracy.

Figure 1 shows the circuit implemented by the board. Refer to the individual amplifier data sheets for a detailed description of operation. Briefly, however, the DriveR amp topology achieves an equivalent output impedance without the need for a discrete matching resistor in series with the output. The CLC560/561 are primarily intended for non-inverting applications with the input impedance set by \( R_{\text{in}} \). \( R_\text{g} \) primarily determines the output impedance while \( R_\text{o} \), having set a particular \( R_\text{o} \), will set the no load gain. The actual voltage gain to the load must also include any voltage divider effect from the output impedance to the load. Figure 2 summarizes the design equations for achieving a desired output impedance and gain. Note that an external compensation capacitance, \( C_\text{x} \), must be included for flat frequency response. The equation shown assumes a load matched to the output impedance.

Several optional features are included in the schematic of Figure 1. First, since reversed supplies will destroy the CLC560/561 amplifiers, a provision for series diodes (type IN4002 or equiv.) has been provided on the board. If D1 and D2 are inserted into the board, the power supply traces in parallel should be cut. Dropping the power supply voltage through these diodes will slightly decrease the full scale output voltage swing and worsen the 2nd harmonic distortion by about 1dB.

Second, it is sometimes advantageous to implement a portion of the desired output impedance with a discrete series resistor in the output, \( R_x \). Inserting an \( R_x \) into the board will require the output trace on the opposite side of the board from \( R_x \) to be cut. Using \( R_x \) will decrease the achievable swing at the load, but will improve the output VSWR as shown in the data sheet plots and help protect the part from output short circuit damage.

The evaluation board has been layed out with careful attention to frequency response, distortion characteristics, and thermal management (see Figure 3, 4, and 5). Specially, a continuous ground plane beneath the part has been maintained to allow the use of thermally conductive pad beneath the part as described in the device data sheets. Using this pad to conduct heat into the board, greatly decreases the case temperature in operation. Also, the .1\mu F supply decoupling capacitors have been carefully placed to achieve a very symmetric ground return path (through the ground plane under the part) to the output load. This is very critical to achieving the specified 2nd harmonic distortion. Finally, the compensation capacitor has been placed to achieve the broadest bandwidth capability for a single sided component loading scheme.

**SUMMARY DESIGN EQUATIONS AND DEFINITIONS**

\[
R_\text{f} = (G + 1)R_\text{g} - A_\text{V}R_\text{f} \\
R_\text{g} = \frac{R_\text{f} - R_\text{g}}{A_\text{V} - 1} \\
R_\text{g} \ - \ Gain \ setting \ resistor \ from \ inverting \ input \ to \ ground \\
C_\text{x} = \frac{1}{300(1 - \frac{2}{R_\text{g}})} \cdot .08 \\
C_\text{x} \ - \ External \ compensation \ capacitor \ from \ output \ to \ pin \ 19 \ \text{(in pF)}
\]

Where:

- \( R_\text{o} \) - Desired equivalent output impedance
- \( A_\text{V} \) - Non-inverting input to output voltage gain with no load
- \( G \) - Internal current gain from inverting input to output = 10 ± 1%
- \( R_\text{f} \) - Internal inverting input impedance = 14\Omega ± 5%

Description
The CLC92X evaluation board (Comlinear part number 730015) is designed to support simple, effective evaluation of the converter. It uses a standard Eurocard connector to make power, ground, and digital connections. Although the board is labelled as a CLC925 Evaluation Board, it can also accommodate the CLC922 and CLC926 ADC's.

Power and Ground
The power supply and ground connections to the Eurocard connector should be as short as possible in order to minimize power supply resonances.

The CLC92X has a well-designed power and ground system internal to the device. Nonetheless, care should be used when adding peripheral digital circuitry to avoid corrupting the ground plane by injecting large amounts of digital switching noise into the ground plane near the CLC92X.

+15V is not used in the CLC922 (Pin 34). For this reason J1-A26, B26 may be connected to ground, connected to +15V, or left open.

Inputs
The convert signal may be provided through the Eurocard connector or through a standard SMA connection on the board. The analog input signal is provided through an SMA connector.

Outputs
For applications requiring a high degree of drive capability (such as driving long lengths of ribbon cable), external TTL drivers with greater drive capability should be used.

Convert Clock
In order to maintain the signal-to-noise performance, the phase noise (or jitter) of the convert pulse must be kept as low as possible. See the CLC92X data sheet for a more complete discussion.

Schematic and Component Placement
The schematic and component placement guide for the evaluation board are shown below.

Figure 1: Evaluation board schematic
Figure 2: Component placement guide

Note: It is important to carefully note the location of pin #1 on the evaluation board and to insert the CLC92X correctly.

Parts List

CLC92X 12-bit, 10MSPS A/D
730015 printed circuit board

J1 64-pin Eurocard connector male:
Winchester 64P-6033-0431-0
(matching female connector: Winchester 64S-6033-0422-1)

J2, J3 SMA connector, female Amphenol 901-144 or equivalent

R1 50Ω, 1/8W metal film
R2 optional (may be used to terminate convert clock)
R3 1kΩ, 1/8W metal film

C1, C2, C3 6.8μF tantalum capacitor (Sprague 1500 series or equivalent)

C4-C11 0.1μF ceramic radial lead

L1, L2, L3 jumper wires

socket 2 pieces Samtec SL-120-T-30

A1 jumper wires (optional)

*The convert clock is connected to the Eurocard connector only when jumper A1 is installed.

Note: Not required when using a CLC922.
Description
The CLC935 evaluation board has been designed as an effective evaluation platform for the CLC935 (12-bit, 15MSPS) the CLC936 (12-bit, 20MSPS), and the CLC937 (12-bit, 25.6MSPS) analog-to-digital converters. Connections are made using a standard Eurocard connector for digital and power signals, and standard SMA connectors for the sensitive conversion clock and analog signals.

The board is available blank (part number 730025) and fully assembled (part number E935PCASM). The E935PCASM includes a socket for the CLC935/6/7, but does not include the CLC935/6/7.

Power and Ground
Power supply and ground connections to the Eurocard connector should be kept as short as possible to minimize power supply resonances. Additionally, switching power supplies are strongly discouraged for applications requiring maximum performance.

The converters digital and analog grounds are connected via the analog ground plane. The DATA READY and D1-D14 output drivers have a separate digital ground plane and -5.2V power feed. The two "GND" jumpers can be used to connect the converter and digital ground planes together (the E935PCASM is configured with both ground planes connected via the "GND" jumpers). This arrangement should facilitate ground-loop creation or elimination, as required, to minimize digital system noise corruption of the converter and any associated analog circuitry. Digital ground is available through the Eurocard connector at pins 2A/B and 19A/B. Analog ground is available through the Eurocard connector at pins 27A/B and 28A/B.

Analog Input
The ANALOG INPUT is provided through the SMA connector J1. The E935PCASM employs a 50Ω input termination resistor. Values larger than 200Ω are not recommended unless driven by a low-impedance analog input source. Often in evaluating converters, the ANALOG INPUT is driven by a single-tone source. It should be noted that any jitter present in this source will undermine the apparent quality of the conversion process, specifically SNR (signal-to-noise ratio). To avoid this situation, a very-low noise (low jitter) signal source should be used to provide the ANALOG INPUT signal. Bandpass filtering will likely be required given the generally high harmonic content of very-low noise signal sources.

CONVERT Clock Source
The evaluation board employs an ac-coupled sine-to-ECL converter. The input can come from either the Eurocard connector or the SMA connector J2. In normal operation, the circuit will function very well with a 2Vpp input signal. To maintain the specified SNR performance, a very-low phase noise (low jitter) signal source is absolutely essential in providing the CONVERT signal. Bandpass filtered crystal oscillators or low phase noise synthesizers such as the HP8662 or Fluke T6160B are suitable choices.

The CONVERT clock can be supplied through the Eurocard connector at pins 1A/B. U6 can be left in-circuit if buffering of the CONVERT signal is desired. Some "patch" wiring will be required to provide adequate termination of the Eurocard derived signals. It should be noted that the converter references the CONVERT input to analog ground. Please refer to the schematic on the following pages.

Outputs
The CLC935/6/7 converters employ "constant current" ECL compatible outputs. This unique design minimizes noise inside the hybrid, but requires buffering, preferably near the converter. The evaluation board employs MC100E151 hex latches to perform this function.

Although no termination resistors are needed for the CLC935/6/7, the 100E151’s, however, do require standard ECL terminations. Having been setup as differential outputs through the Eurocard connector, it is expected that the user will provide suitable ECL terminations on the receiving side of the evaluation board connector. Simple 390Ω pull-down resistors to -5.2V have proven effective given the speed range of the CLC935/6/7 converters.

The DATA READY signal is also available from the Eurocard connector. This signal is derived in such a way as to minimize any loading or distortion effects on the CONVERT signal used for the converter itself. The DATA READY signal is also used to clock the output latches U3 to U5, and has been terminated on board. If desired, the DATA READY termination can be relocated to a more appropriate position in the evaluation system.

The output coding of the converter is controlled through two jumpers. The MSB and MSB jumper determines which of the converter’s MSB outputs is presented to the latches, while JP1 controls the inversion of the LSB’s (D2 to D12). The E935PCASM comes configured for binary output with the MSB jumper installed. Please refer to the CLC935/6/7 data sheet for more details on output coding.

Description

An evaluation board is available for the CLC940, P/N 730011. The board is user-configurable for either TTL or ECL operation (see Figure 4).

On the board near pin 1 of the CLC940 are four points labeled "A," "H," "B," and "T" (see Figures 4 and 5). Jumpers are connected between these points to provide the CLC940 with the bias voltages needed for single-ended ECL and TTL. Points "H" and "T" go to the "hold" and "track" inputs, respectively. Point "A" goes to the "digital input," and "B" goes to the TTL/ECL bias network.

The connection scheme for TTL requires that the bias network provide +1.4V at point "B." The +15V supply is used and the diodes are inserted so as to be forward biased (see Figures 2 and 4). Jumpers are used to connect "A" to "H" and "B" to "T."

Single-ended ECL is connected similarly, however the bias network should be configured to provide -1.4V at point "B." The -15V supply is used and the diodes are inserted so as to be forward biased (see Figures 2 and 4). Jumpers are used to connect "A" to "H" and "B" to "T."

For differential ECL, signals can be sent directly to points "H" and "T," the "hold" and "track" inputs respectively. The bias circuit and jumper connections should be omitted (see Figures 1 and 4).

The resistor at the digital input, $R_D$, is omitted for TTL and ECL, but is otherwise used to set the (digital) input impedance. The resistor at the analog input, $R_{in}$, is selected for the desired input impedance. The output resistor, $R_{out}$, is selected for the desired output impedance and for optimum capacitive-load performance (see the $R_{out}$ vs. Load Capacitance plot on the plot page of the data sheet).

January 1993
Description
The CLC942 is a 12-Bit accurate, fast sampling, wideband track-and-hold amplifier which offers ultra-fast switching performance plus an unprecedented array of supporting specifications.

The CLC942 evaluation board (Comlinear part number 730017) is designed to support simple, effective evaluation of the CLC942 track-and-hold.

The board is user-configurable for TTL or ECL operation. The track/hold input may also be configured for a nominal input threshold of zero volts.

Power Supplies
The CLC942 uses +15V, +5V, and −5.2V supplies. If desired, −5V can be substituted for the −5.2 supply without degrading performance.

Inputs and Outputs
SMA connections are used to connect the track/hold input (SMA1), signal input (SMA2) and output (SMA3).

Track/Hold Input
The track/hold input may be set up for nominal TTL and ECL thresholds. In addition, it may be set up for a zero volt threshold. (See schematic for details.)

In order to maintain best signal to noise, the phase noise (or jitter) of the track/hold input must be kept as low as possible. Crystal oscillators or low phase noise synthesizers such as the HP8662 or Fluke T6160B are suitable.

PART DESCRIPTION: Several thermally conductive pads for use between several hybrid product packages and a top surface ground plane to enhance heat conduction to the external environment.

These are all SIL-PAD 200 material with adhesive on one side. Part numbers are Comlinear part numbers at Bergquist.

Part Number: 550007
Used for 40-pin, 1.1" wide ceramic DIP package (e.g. CLC922, 925, 926, 935, 936). Thermal impedance 2.6°C - in²/W (typical).

Part Number: 550006
Used for 24-pin, 0.6" wide ceramic DIP package (e.g. CLC560, 561, 942). Thermal impedance 2.6°C - in²/W (typical).

Part Number: 550009
Used for 12-pin, TO-8 package (e.g. CLC231, 205, 206, 207, etc.) Thermal impedance 2.0°C - in²/W (typical).

ORDER PLACEMENT
Orders may be placed and information obtained from either your area representative or distributor, via telephone, facsimile and mail, or by contacting Comlinear directly.

If it is determined that a "special" product is required, such as SCD (Specification Control Drawing) products, custom products or specially tested products, we recommend that you call your area representative or the Comlinear Sales Support Group.

In order to provide maximum service and satisfaction, products should be ordered in their country of end use.

Customers requiring formal paperwork such as pro forma invoices or quotations can receive immediate assistance from your area representative or distributor.

When placing your order, please provide as a minimum, the purchase order number, model number, and ship-to and bill-to addresses.

TERMS OF SALE
All shipments are FOB, Fort Collins, Colorado. Comlinear's standard terms are NET 30 days inside the U.S.A. Terms for customers outside the U.S.A. are irrevocable letters of credit or cash in advance unless other terms have been arranged. Detailed standard terms and conditions of sale are available upon request.

TECHNICAL ASSISTANCE
Comlinear is dedicated to providing innovative solutions to high-speed signal processing challenges. To support this effort, Comlinear maintains a staff of research-and-development-level applications engineers, to provide both technical and design assistance. Their experience, laboratory, and computer simulation resources uniquely qualify them to assist you.

SALES SUPPORT
Comlinear's solution to your signal processing needs continues with fast local support of your ordering and product availability needs. Comlinear maintains a network of highly qualified representatives and distributors, covering the United States, Canada, Europe, and Asia. For further information, Comlinear's in-house Sales Support staff is available to assist you. A complete listing of representatives and distributors is located in Section 16 of this databook.

RETURN AND WARRANTY INFORMATION
If for any reason, a product must be returned to Comlinear, a Return Material Authorization (RMA) should be used. This can be obtained by contacting your area representative, distributor, or Comlinear. The product should then be shipped prepaid to the Fort Collins, Colorado, facility for evaluation or repair. It is requested that a description of the problem and the specific application be included in the return.

All Comlinear Corporation products are warranted against defects in workmanship and materials under normal use for a period of one year from the date of manufacture. Comlinear shall have the option after evaluation to either replace or repair the defective product. This warranty does not apply to any products which have been subject to misuse (including ESD damage), neglect, accident or modification, or that have been soldered or altered during assembly, and are not capable of being tested by Comlinear under normal test conditions.

For additional warranty information, please refer to Comlinear's Standard Terms and Conditions of Sale (available upon request).
