ALTO OPERATING SYSTEM
REFERENCE MANUAL

Compiled on: December 15, 1980

Xerox Palo Alto Research Center
3333 Coyote Hill Road
Palo Alto, California 94304
1. Introduction

This manual describes the operating system for the Alto. The manual will be revised as the system changes. Parts of the system which are likely to be changed are so indicated; users should try to isolate their use of these facilities in routines which can easily be modified, or better yet, avoid them entirely, if possible.

The system and its description can be separated into two parts:

a) User-callable procedures, which are of two kinds: standard procedures which are always provided, and library procedures which must be loaded with the user's program if they are desired. This manual describes only standard procedures; the library procedures are documented in the "Alto Packages Manual."

b) Data structures, such as disk files and directories, which are used by the system but which are also accessible to user procedures and subsystems.

The system is written almost entirely in Bepl. Its procedures are invoked with the standard Bepl calling sequence, and it expects the subsystems it calls to be in the format produced by the Alto Bepl loader.

2. Hardware summary

This section provides an overview of the Alto Hardware. Briefly, every Alto has:

a) A memory of 64k words of 16 bits each. The cycle time is 850ns.

b) An emulator for a standard instruction set.

c) Secondary memory, which may consist of one or two Diablo 31 cartridge disk drives, or one Diablo 44 cartridge disk drive. The properties of these disks are summarized in Table 2.2.

d) An 875 line TV monitor on which a raster of square dots can be displayed, 606 dots wide and 808 dots high. The display is refreshed from Alto memory under control of a list of display control blocks. Each block describes what to display on a horizontal band of the screen by specifying:
   the height of the band, which must be even;
   the width, which must be a multiple of 32; the space remaining on the right is filled with background;
   The indentation, which must be a multiple of 16; the space thus reserved on the left is filled with background;
   the color of the background, black or white;
   the address of the data (must be even), in which 0 bits specify background. Each bit controls the color of one dot. The ordering is increasing word addresses and then bit numbers in memory, top to bottom and then left to right on the screen; and a half-resolution flag which makes each dot twice as wide and twice as high.
There is also a 16 x 16 cursor which can be positioned anywhere on the screen. If the entire screen is filled at full resolution, the display takes about 60% of the machine cycles and 307041D words of memory.
e) A 44-key keyboard, 5-finger keyset, and mouse

f) A Diablo printer interface

g) An Ethernet interface

h) Interfaces for analog-to-digital and digital-to-analog conversion, for TV camera input, and for a RS-232b (teletype) connection

i) A real-time clock and an interval timer (see table 2.1 for brief descriptions)

3. User-callable procedures

This section describes the operating system facilities provided by procedures which can be called from user programs using the standard Bcpl calling sequence. All of these procedures are a permanent part of the operating system, automatically available to any user program.

Although this manual describes a rather extensive set of facilities, which together occupy close to 12K words of memory, portions of the system can be deactivated (see Junta), thus freeing the memory they use. When the user program finishes execution, the deactivated portions can be retrieved from the disk and reinitialized.

Default arguments: Many of the procedures given below have rather long argument lists, but have convenient defaulting schemes. The documentation decorates argument lists with default values. An argument followed by [exp] will default if omitted or zero to the value exp; an argument followed by [...exp] will default if omitted to exp. Although Bcpl allows you to omit procedure arguments by using "nil," the called procedure cannot detect its use; it therefore cannot be the basis for defaulting arguments.

3.1. Facilities

The facilities of the operating system fall into fairly neat categories; often this is because the operating system has simply loaded a standard library subroutine as part of its environment. This manual offers summarized documentation for the functions in the various software "packages;" more documentation can be found in the "Alto Software Packages Manual." (Note: Appendices to this manual include documentation of the packages most relevant to the operating system.) In outline, the operating system provides:

- A "basic" resident that maintains a time-of-day clock, that processes parity error interrupts, and that contains the resident required to interface to Swat, the debugger.

- The Bcpl runtime support module, which provides several functions (such as a stack frame allocator) that are necessary to permit Bcpl programs to run.

- Disk drivers for transferring complete pages between memory and existing files on the disk. This is the BfsBase package.

- Disk drivers for creating new files, and for extending or shortening existing files. This is the BfsWrite package.

- A simple storage allocator for managing "zones" of working storage. This is the Alloc package.

- Disk "streams," which implement sequential byte or word I/O to the disk. This is the DiskStreams package.

- Disk directory management, which provides facilities for searching directory files for entries that associate a string name and a disk file.
- A keyboard handler, which decodes keyboard interactions into a sequence of ASCII characters.

- A display driver, which maintains a "system display," and handles the printing of characters on the display. This is the DspStream package.

- Miscellaneous functions, including (1) the "call subsystem" function, which reads a file produced by the Bcpl loader into memory and executes it; (2) allocation functions that manage the space not used by the operating system or the user code, providing a stack for the user program and fixed-size blocks that it may require; (3) the procedure for de-activating various portions of the operating system; and (4) additional utilities.

3.2. Loading and Initialization

The facilities of the operating system are made accessible to user programs via static variables that refer to system procedures or system scalars. Because these objects are not defined in your Bcpl program, you must declare the names to be external. The Bcpl loader, Bldr, automatically reads the file Sys.Bk, which describes how to arrange that your program's external references will match up with the operating system objects (for details, see Bldr documentation in the Bcpl manual). This arrangement does not require reloading programs when objects in the operating system move.

When a Bcpl program is read into the Alto memory, all of the system procedures described below will have been initialized. A region is reserved for allocating system objects (e.g., disk streams); currently, about 6 disk streams or equivalent can be accommodated. If the space reserved is inadequate for your application, the system zone can be replaced with one constructed by your program. In addition, most procedures that create system objects have provision for an optional "zone" argument used for seizing space (see section 4.5).

3.3. Errors

Whenever the system detects an error for which the user program has not supplied its own error routine, the call SysErr(p1, errCode, p2, p3, ...) is executed. The errCode is a number that identifies the error; the p’s are parameters that add details.

Normally, SysErr calls Swat (the debugger), which will print out an intelligible error message retrieved from the file Sys.Errors. The facilities of Swat (see "Alto Subsystems Manual") can then be used to interrogate the program state more fully, and ultimately to continue or abort its execution.

3.4. Streams

The purpose of streams is to provide a standard interface between programs and their sources of sequential input and sinks for sequential output. A set of standard operations, defined for all streams, is sufficient for all ordinary input-output requirements. In addition, some streams may have special operations defined for them. Programs which use any non-standard operations thereby forfeit complete compatibility.

Streams transmit information in atomic units called items. Usually an item is a byte or a word, and this is the case for all the streams supplied by the operating system. Of course, a stream supplied to a program must have the same ideas about the kind of items it handles as the program does, or confusion will result. Normally, streams which transmit text use byte items, and those which transmit binary information use words. (The 16-bit quantity which Bcpl passes as an argument or receives as a result of a stream operation could be a pointer to some larger object such as a string, although the operating system implements no such streams. In this case, storage allocation conventions for the objects thus transmitted would have to be defined.)

You are free to construct your own streams by setting up a suitable data structure (section 4.2) which provides links to your own procedures which implement the standard operations.
The standard operations on streams are (S is the stream; "error" means that Errors(S, cc) is executed, where cc is an error code):

- **Gets(S)** returns the next item. Some streams give an error if Endofs(S) is true before the call, and others just wait for the next item.

- **Puts(S, I)** writes I into the stream as the next item; error if the stream is read-only, or if there is no more space or if there is some hardware problem.

- **Resets(S)** restores the stream to some initial state, generally as close as possible to the state it is in just after it is created.

- **Putbacks(S, I)** modifies S so that the next Gets(S) will return I and leave S in the state it was in before the Putbacks. Error if there is already a putback in force on S. (No streams provided by the operating system implement a Putbacks operation.)

- **Endofs(S)** true if there are no more items to be gotten from S. Not defined for output streams.

- **Closes(S)** destroys S in an orderly way, and frees the space allocated for it. Note that this has nothing to do with deleting a disk file.

- **Stateofs(S)** returns a word of state information which is dependent on the type of stream.

- **Errors(S, cc)** reports the occurrence of an error with error code cc on the stream. When a system stream is created, Errors is initialized to SysErr (see section 3.3), but the user can replace it with his own error routine.

Streams are created differently depending on the device being accessed (disk, display, keyboard, or memory). The procedures for creating streams are described below.

### 3.4.1. Disk streams

The system distinguishes four kinds of object which have something to do with storing data on the disk:

- **Disk Pack:** A storage medium that is capable of storing data in various pages. Most operating system functions default the choice of disk to "sysDisk", a structure which describes drive 0 of a Diablo model 31 cartridge.

- **Disk file:** A vector of bytes of data held on some disk, organized into pages for some purposes. A file exists only on the disk (except that parts of it may be in memory if an output stream is associated with it) and is named by an 80-bit entity called a file pointer (FP).

- **File directory:** A disk file which contains a list of pairs <string name, FP>. Documentation on the format of the file can be found with the BFS package documentation contained in an appendix to this manual.

- **Disk stream:** Used by a program to transfer information to or from a disk file. A stream exists only in memory and is named by a pointer to a data structure.
The procedures that operate on disk streams are described in documentation for the "DiskStreams" software package contained in an appendix to this manual. Below is a summary list of the functions (in addition to the generic functions described above):

CreateDiskStream(filePtr, type [ksTypeReadWrite], itemSize [wordItem], Cleanup [Noop], errRtn [SysErr], zone [sysZone], nil, disk [sysDisk]) = a disk stream, or 0 if an error is encountered while initializing the stream. filePtr is the sort of object stored in a file directory. Legal types are ksTypeReadOnly, ksTypeReadWrite, and ksTypeWriteOnly. Legal item sizes are wordItem and charItem.

CleanupDiskStream(s) = Flush any buffers to the disk.

ReadBlock(s, address, count) = actualCount. Read up to count words from the stream into consecutive memory locations; return the actual number of words read. (Non-intuitive things happen at the end of a file with an odd number of bytes -- read the documentation carefully)

WriteBlock(s, address, count) Write count words from consecutive memory locations onto the stream.

LnPageSize(s) = log (base 2) of the page size, in words, of the files manipulated by the stream.

GetPositionPage(s, page) Positions the file to byte 0 of the specified page (page 1 is the first data page).

GetPositionPtr(s, byteNo) Positions the file to the specified byte of the current page.

FileLength(s, filePos []) = Length. Returns number of bytes in file; positions stream to the last byte.

FilePos(s, filePos []) = Pos. Returns the current byte position in the file.

SetFilePos(s, filePos or SetFilePos(s, HighOrder, LowOrder) Sets the position of the file to the specified byte.

GetCurrentFa(s, fileAddress) Returns the current file address.

JumpToFa(s, fileAddress) Positions the file to the specified address (usually obtained from GetCurrentFa).

GetCompleteFa(s, completeFileAddress) Returns a complete file address, including a filePtr.

TruncateDiskStream(s) Truncates the file to the current position.

ReadLeaderPage(s, address) Reads the 256-word leader page of the file into consecutive locations starting at address.

WriteLeaderPage(s, address) Writes 256 words onto the leader page of the file.

The operating system also contains a package for dealing with files at a lower level, the "Bfs" (Basic file system) package.

Disk Errors: The system will repeat five times any disk operation which causes an error. On the last three repetitions, it will do a restore operation on the disk first. If five repetitions do not result in an error-free operation, a (hard) disk error occurs; it is reported by a call on Errors for the stream involved.
3.4.2. Display streams

Display streams are implemented with the "DspStream" package, described in separate documentation contained in an appendix to this manual. Below is a list of the functions included (in addition to the generic stream functions):

- **CreateDisplayStream(nLines, pBlock, bBlock, Font [sysFont], wWidth [38], options [DScompactLeft+DScompactRight], zone [sysZone])** = a display stream. pBlock is the address of a region bBlock words long for the display bitmap. nLines is the number of text lines in the stream. This procedure does not commence displaying the stream text -- see ShowDisplayStream.

- **ShowDisplayStream(s, how [DSbelow], otherStream [dsp])** This procedure controls the presentation of the stream on the screen. If how is DSbelow, the stream will be displayed immediately below otherStream; if DSabove, immediately above; if DSalone, the stream will become the only display stream displayed. If how is DSdelete, the stream s will be removed from the display. For DSalone and DSdelete, the third argument is needless.

- **SetFont(s)** Returns current font.

- **SetFont(s, font)** Sets current font (use carefully -- see documentation).

- **ResetLine(s)** Erases all information on the current line and resets the position to the left margin.

- **GetBitPos(s)** Returns the horizontal position of the stream.

- **SetBitPos(s, pos)** Sets the horizontal position on the current line (use carefully -- see documentation).

- **GetLinePos(s)** Returns the index of the line into which characters are presently being put.

- **SetLinePos(s, pos)** Sets the line number into which subsequent characters will be put.

- **InvertLine(s, pos)** Inverts the black/white sense of the line given by pos.

- **EraseBits(s, nBits, flag [0])** Erase bits moving forward (nBits>0) or backward (nBits<0) from the current position. Set to background if flag=0; to the complement of the background if flag=1; invert present values if flag=-1.

- **GetLmarg(s); SetLmarg(s)** Get and set left margin for the current line.

- **GetRmarg(s); SetRmarg(s)** Get and set right margin for the current line.

- **CharWidth(StreamOrFont, char)** Get the width of the character, using the specified font or the current font in the specified stream.

The "system display stream" is always open, and can be accessed by the system scalar "dsp."
3.4.3. Keyboard Streams

There is a single keyboard stream in which characters are buffered. The stream is always open, and may be accessed through the system scalar "keys." The only non-null operations are GetS; Endofs, which is true if no characters are waiting; and Resets, which clears the input buffer.

The keyboard handler periodically copies the mouse coordinates into the cursor coordinates, truncating at the screen boundary. This function is governed by the value of a cell referenced by @lvCursorLink; if it is zero, the function is disabled.

Low-level keyboard functions. Although the standard keyboard handler contains no facilities for detecting transitions of keysets or mouse keys, a user function may be provided that will be called 60 times a second and can extract relevant information from a table passed to it. The call SetKeyboardProc(uKbProc, stack, stackLength) will install uKbProc as the user procedure; stack is a vector that will be used for stack space when uKbProc is run (you must provide enough). SetKeyboardProc() will reset the keyboard handler, and cease calling uKbProc. (Note: If the program has used the Junta procedure, the user keyboard procedure must be deactivated during a CounterJunta or finish unless all its state lies below OsFinish<safeAddr>.) If active, every 16 milliseconds, the keyboard handler will execute uKbProc(tab), where tab points to a data structure defined by the KBTRANS structure (see the file SysDefs.d). The Transition word is non-zero if a key transition has been detected; GoingUp or GoingDown tell which sort of transition has occurred; and KeyIndex gives the key number. KeyState is a 5-word table giving the state of the keys after the transition has occurred: if a key with KeyIndex=1 is presently down, bit (i rem 16) of word (i div 16) will be 1. The entries CursorX and CursorY give the current location of the cursor.

The value returned by uKbProc determines subsequent processing. If true is returned, the operating system treats the key transition (if any) according to normal conventions. If false is returned, the operating system assumes that uKbProc has performed whatever processing is intended, and the interrupt is simply dismissed.

KeyIndex values are tabulated below. Keys are normally given by their lower-case marking on the key top; those with more than one character on their tops are specified by <name>. <XX> are unused bits; <blank-top> is the key to the right of the <bs> key; <blank-middle> to the right of <return>; and <blank-bottom> to the right of <shift-right>.

Values  Keys

0-15  5 4 6 e 7 d u v o k - p / \  <lf> <bs>
16-31 3 2 w q s a 9 i x 0 . , ] <blank-middle> <blank-top>
32-45 1 <esc> <tab> f <ctrl> c j b z <shift-left> ; <return> + <del> <x>
48-63 r t g y h 8 n m <lock> <space> [ = <shift-right> <blank-bottom> <x> <x>
64-71 unused
72-76 Keyset keys in order, left = 72; right = 76
77  RED (or left or top) mouse button
78  BLUE (or right or bottom) mouse button
79  YELLOW (or middle) mouse button

As an aid to interpreting KeyIndex values, the system scalar kbTransitionTable points to a table, indexed by KeyIndex, that gives a KBKEY structure for the key; if it is zero, the operating system has no standard interpretation of the key.

3.4.4. Fast Streams to Memory

The operating system also contains procedures that allow very efficient stream I/O to memory blocks. These functions, described in the Streams package documentation, allow one for example to use more memory buffering for disk transfers than normally allocated by the disk stream mechanism.
3.5. Directory Access

Most user programs do not concern themselves with file pointers, but use system routines which go directly from string names to streams. By a "file name" we mean a string which can be converted into a file identifier by looking it up in a directory. File names are arbitrary fcpI strings which contain only upper and lower case letters, digits, and characters in the string "+-.!$". File names are stored in directories as they are typed, but no distinction is made between upper and lower case letters when they are looked up. Dots (".") are used to separate file names into parts. If there is more than one part, the last part is called the extension, and is conventionally used much like extensions in Tenex.

There is an optional version number facility. It is not available in the standard release of the operating system (NewOs.boot), but is available in an unsupported alternate version (NewOsV.boot). If the version number facility is enabled, the interpretation of exclamation mark ("!" ) is special; if a file name ends with a ! followed only by digits, the digits specify the file version number.

A lookup name, presented to one of the directory functions given below, is usually a file name. However, it may optionally specify the name of a directory in which to look for the file (or record the new file). The lookup name is processed from left to right. If the character "<" appears at the head of the lookup name, the system directory ("SysDir.") becomes the "current" directory; whenever the character " >" follows a name, the name is looked up in the current directory and that file becomes the new current directory. If no directory is specified in the lookup name, the "working directory" is assumed. Example: "<dir>fil." will look up dir in the system directory SysDir, and will then look up fil in dir. Any illegal characters in a lookup name are replaced with ".." characters.

File Versions: The file system also supports multiple versions of the same file; this feature may be enabled or disabled when the operating system is installed. The version number is recorded by appending an exclamation mark and the decimal version number to the file name; file names without version numbers appended act as if they are "version 0." The OpenFile function uses lookup names and version control information to locate a desired file. If the lookup name contains a version number (e.g., "Sys.Errors!3."), then no version defaulting is done--the lookup operates on precisely the file specified. (This processing is identical with versions enabled and disabled.)

If the lookup name does not specify a version number and file versions are enabled, then the versionControl parameter specifies how defaulting is to be done (in the definitions, "oldest" refers to the file with the "lowest" version number; "latest" refers to the file with the "highest" version number):

- **verLatest**
  - The latest version is used.

- **verLatestCreate**
  - The latest version is used. If the file does not exist, it is created with version number 0 (i.e., no number will be appended explicitly to the file name): this is to prevent needless accumulation of version numbers in system-related files (e.g., Run files).

- **verOldest**
  - The oldest version is used.

- **verNew**
  - A new file will always be created. A system parameter, established when the system is installed, determines how many old versions will be preserved. If that default should be overridden, just add the desired number of versions to verNew, e.g. a versionControl value of verNew+4 will create a new file and retain at most three older versions.

  This version option may reuse disk pages allocated for the oldest version of the file, but the serial number and file name will of course be changed. If (newest-oldest)+1 is greater than or equal to the number of versions to keep, oldest is reused in this fashion to become version newest+1. For example, if verNew is specified, 2 versions are to be kept, and foo2 and foo3 exist,
verNew will create the file foo14 by remaking the old file foo12. Note that this calculation does not verify that all versions between oldest and newest actually exist.

If only one file matches the lookup name, and its version number is 0, the file is simply overwritten (like verLatestCreate); a new version is not created.

If no files of the given name exist, version number 0 of the file is created (i.e., no version number is explicitly attached to the file name). The verNewAlways option (below) can be used if version 1 should be created.

verNewAlways

Similar to verNew, but if no earlier version of the file exists, version 1 is created.

If versions are not enabled, then exact matches are performed on the entire file name. Thus, if the file "Sys.Errors12" is present on a disk with versions disabled, the lookup name "Sys.Errors" will not match this file; the lookup name "Sys.Errors12" will. The versionControl parameter is still relevant: if no file matching the lookup name is found, verLatest and verOldest will not create a new file, whereas the other versionControls will.

The following function creates a disk stream (see above) in conjunction with the Alto directory structure:

OpenFile(lookupname, ksType [ksTypeReadWrite], itemSize [wordItem], versionControl [if ksType=ksTypeReadOnly then verLatest else if ksType=ksTypeWriteOnly then verNew else verLatestCreate], hintFp [0], errRtn [SysErr], zone [sysZone], nil, disk [sysDisk], CreateStream [CreateDiskStream]) = a disk stream, open on the specified file, or 0 if the open is unsuccessful for some reason. This routine parses the lookup name, searching directories as needed. After applying version control (e.g., making a new version), it calls CreateStream(filePointer, ksType, itemSize, Noop, errRtn, zone, nil, disk), and returns the value of that call.

If hintFp is provided, it is assumed to be a file pointer (FP) that "hints" at the correct identification of the file. Before searching a directory, OpenFile will try using the hint to open the file, quickly returning a stream if the hint is valid (though no name or version checking is done). If the hint fails and lookupname is non-zero, the name will be parsed and looked up in the normal fashion, hintFp will be filled in with the correct file pointer. Note: If you wish to use standard file lookup procedures, but to have the FP for the resulting file returned to you, zero the hintFp vector before calling OpenFile. In this case, the value of hintFp is not used in the lookup, but is filled in with the results.

OpenFileFromFp(hintFp) = OpenFile(0, 0, 0, 0, hintFp)

DeleteFile(lookupname, versionControl [verOldest], errRtn [SysErr], zone [sysZone], nil, disk [sysDisk]) = success. Deletes the file on the disk and removes the corresponding entry from the directory specified in lookupname. Returns "true" if a file was correctly found and deleted, otherwise "false."

SetWorkingDir(name, fp, disk [sysDisk]) Sets the "current" directory for further lookups on the given disk. When the system is booted, the current directory is set to "<SysDir."
3.5.1. Lower-level directory functions

Several functions are provided for those who wish to deal with directories and file names at a lower level. The format of an Alto file directory is documented in the Disks documentation; definitions appear in AltoFileSys.d.

ParseFileName(destName, srcName, list, versionControl) = stream or 0. Strips leading directory information from srcName, puts the result in destName, appending a "." if necessary, and returns a stream open on the directory in which the file should be looked up. list!0 = an errorRoutine, list!1 = a zone, list!3 = a disk which will be passed to OpenFile along with versionControl when opening the directory stream.

FindFdEntry(s, name, compareFn [0], dv [], hd [], versionControl [verbatim], extraSpace [0]) = a word pointer into the stream s of a directory entry, or -1 if no entry is located. If compareFn is 0, normal comparison of file names and version control is performed; the result is a directory entry in dv, and a hole descriptor (hd) for a hole large enough to include the name, a new version number, and extraSpace words.

Otherwise, compareFn is a user procedure that is invoked as each file name is read from the directory: compareFn(name, nameRead, dvRead). nameRead is the Bcpl name extracted from the directory; dvRead is the dv extracted from the directory; and name is simply the second argument passed to FindFdEntry (which need not be a string). If compareFn returns false, the directory scan halts; the value of FindFdEntry is the byte position in the stream. If compareFn returns true, the search proceeds.

Strategic note: If compareFn is TruePredicate, the directory is simply scanned in order to locate a hole large enough for extraSpace words. The result is saved in the hd hole descriptor, which may be passed to MakeNewFdEntry.

In the standard release of the operating system (version numbering absent), the directory stream is left positioned at the matching directory entry if one was found and at the position described by hd otherwise.

MakeNewFdEntry(s, name, dv, hd, extraStuff) makes a directory entry; dv is a pointer to a DV structure for the first part of the entry; name is a Bcpl string that is recorded after the entry (this string must be a legal internal file name, with the dot "." appended), and extraStuff is a pointer to a vector of additional stuff that will be entered following the name. The hd parameter is a pointer to a "hole descriptor" as returned from FindFdEntry.

DeleteFdEntry(s, pos) Deletes the directory entry at byte location pos of the directory open on stream s.

StripVersion(string) = version number. This function strips a version number, if any, from the end of the string argument, and returns the number (0 if no version specified). If, after stripping, there is no final "." on the string, one is appended.

AppendVersion(string, version) Appends a version number and final "." to the string.
WriteDiskDescriptor() If changes have occurred, the copy of the disk descriptor for sysDisk that resides in memory is written onto the disk file "DiskDescriptor."

ReadDiskDescriptor() This function restores the copy of the disk descriptor for sysDisk that resides in memory from the disk file "DiskDescriptor."

3.6. Memory management

Table 3.1 shows the layout of memory. Table 3.2 tells how to obtain the current values of the symbolic locations in Table 3.1. The free space (EndCode to StackEnd) can be manipulated as follows:

GetFixed(nwords) returns a pointer to a block of nwords words, or 0 if there isn’t enough room. It won’t leave less than 100 words for the stack to expand.

FreeFixed(pointer) frees a block provided by GetFixed.

FixedLeft() returns the size of the biggest block which GetFixed would be willing to return.

SetEndCode(newValue) resets endCode explicitly. It is better to do this only when endCode is being decreased.

The allocator is not very bright. FreeFixed decrements endCode if the block being returned is immediately below the current endCode (it knows because GetFixed puts the length of the block in the word preceding the first word of the block it returns; please do not rely on this, however, since there is no guarantee that later allocators will use the same scheme). Otherwise it puts the block on a free list. When another FreeFixed is done, any blocks on the free list which are now just below endCode will also be freed. However, the allocator makes no attempt to allocate blocks from the free list.

3.7. The Alloc allocator

The operating system includes a copy of the Alloc package; documentation is contained in an appendix to this manual.

InitializeZone(start, length, OutOfSpaceRoutine [..SysErr], MalformedRoutine [..SysErr]) = a "zone." These zones are compatible with the "zone" arguments to operating system functions (e.g., sysZone). Allowing MalformedRoutine to default to SysErr causes a through check of the zone data structures to be performed each time a block is allocated or freed. To avoid this (considerable) overhead, pass a zero for the MalformedRoutine. The default sysZone has a MalformedRoutine of SysErr.

AddToZone(zone, block, length) Adds block to the zone.

Allocate(zone, length, returnOnNoSpace [false], even [false]) = pointer to a block of length words allocated from zone. If even is true, the pointer is guaranteed to be a even number.

Free(zone, ptr) Returns the block pointed to by ptr to the zone.

CheckZone(zone) Performs a consistency check on the zone data structure.
3.8. The Basic File System

A set of procedures for driving the disk hardware for Diabio Model 31 and 44 disk cartridges is included in the operating system. These functions are documented in the "Disks" documentation, appended to this manual.

3.9. Objects

It is often convenient to define an abstract object and its operations by a single entity in the Bepl language. As the largest entity Bepl can deal with is a 16-bit number, we must use a pointer to a structure of some kind that defines both the procedures and data associated with the object. Streams, Zones and Disks are examples of such abstract objects. Such objects are typically defined by a structure such as:

```
structure ZN:
{
Allocate word //Op
Free word //Op
Base word //Val
Length word //Val
}
```

where the Op's point to procedures and the Val's are data for the structure. A typical call on one of the abstract procedures is thus (zone>>Z:/N.Allocate)(zone, arg1, arg2, arg3). The virtue of such an arrangement is that any structure that simulates the effects of the procedures can pose as a Zone.

In order to encourage the use of such objects, the operating system has very efficient implementations for this calling mechanism:

```
Call0(s, a, b, ...)
Call1(s, a, b, ...)
Call2, Call3, ..., Call15 analogously.
```

Thus, the operating system defines Allocate = Call0, and Free = Call1, consistent with the Alloc package described above. Note for assembly-language programmers: the CallX functions actually enter the proper function at the second instruction, having already executed a STA 3 1,2 to save the return address.

3.10. Miscellaneous

This section describes a collection of miscellaneous useful routines:

```
Wss(S, string)               writes the string on stream S.
Ws(string)                   writes the string on the system display stream, dsp.
Wl(string)                   Ws(string), followed by a carriage return.
Wns(S, n, nc [0], r[-10])   writes a number n to stream S, converting using radix abs(r). At least nc characters are delivered to the stream, using leading spaces if necessary. The number is printed in signed notation if r<0, in unsigned notation if r>0.
Wos(S, n)                    writes an unsigned octal representation of n on stream S.
Wo(n)                        writes an unsigned octal representation of n on the display stream.
```
TruePredicate() always returns -1.
FalsePredicate() always returns 0.
Noop() null operation; returns its first argument if any.
Dvec(caller, nV1, nV2, ...) this routine allocates "dynamic" vectors in the current frame. caller is the name of the procedure calling Dvec. The use of the routine is best given with an example: the routine ShowOff wants two vectors, V1 and V2:

```plaintext
let ShowOff(V1length, V2length) be
    { let V1 = V1length
      let V2 = V2length
      Dvec(ShowOff, lv V1, lv V2)
      // now V1 points to a block V1length + 1 words long
      // and V2 points to a block V2length + 1 words long
    }
```

Warning: any addresses that point into the stack frame of ShowOff before it is moved by the Dvec call will not be correct after the call. Thus, for example, a "let a = vec 10" before the call will cause the address in a to be useless after the call.

DefaultArgs(lvNa, base, dv1, dv2,...) Utility procedure to fill in default arguments. lvNa points to the "numargs" variable in the procedure; abs(base) is the number of initial arguments that are not to be defaulted; the dv_i are the default values (i<11). If base<0, then an actual parameter of zero will cause the default to be installed; otherwise only (trailing) omitted parameters are defaulted. Thus:

```plaintext
let Mine(how, siz, zone, errRtn; numargs n) be
    { DefaultArgs(lv n, -1, 100, sysZone, SysErr)
    }
```

will default arguments siz, zone, errRtn if missing or zero to 100, sysZone and SysErr respectively. Note that Bcpl will allow you to omit parameters in the middle of a parameter list by using "nil," but DefaultArgs has no way of knowing that you did this.

MoveBlock(dest, src, count) Uses BLT: for i = 0 to count-1 do desti = srci.
SetBlock(dest, val, count) Uses BLKS: for i = 0 to count-1 do desti = val.
Zero(dest, count) Same as SetBlock(dest, 0, count).
BitBlt(bbt) Executes the BITBLT instruction with bbt in AC2.
Usc(a, b) Usc performs an unsigned compare of a and b and returns -1 if a<b, 0 if a=b, 1 if a>b.
Min(a, b), Max(a, b) Returns the minimum or maximum of two signed integers, which must differ by less than 2^15.
Umin(a, b), Umax(a, b) Returns the minimum or maximum of two unsigned integers.
DoubleAdd(a, b)  The parameters a and b each point to 2-word double-precision numbers. DoubleAdd does \( a + a + b \). Note that subtraction can be achieved by adding the two's complement; the two's complement is the one's complement (logical negation) plus 1.

EnableInterrupts() Enables Alto interrupt system.

DisableInterrupts() Disables interrupt system. Returns true if interrupts were on.

StartIO(ac0) Executes the SIO emulator instruction with its argument in ac0. Thus StartIO(#100000) will boot the Alto if it has an Ethernet interface.

Idle() This procedure is called whenever the operating system is waiting for something to happen (e.g., a keyboard character to be struck, or a disk transfer to complete). The static lvIdle points to the operating-system copy of the procedure variable so that programmers may install their own idle procedures by executing "@lvIdle = MyIdle".

Timer(tv) Reads the 32-bit millisecond timer into tv0 and tv1. Returns tv1 as its value.

ReadCalendar(dv) Reads the current date-and-time (32 bits, with a grain of 1 second) into dv0 and dv1. Returns dv as its value. (Subroutines for converting date-and-time into more useful formats for human consumption are available. See subroutine package documentation, under Time.)

SetCalendar(dv) Sets the current date-and-time from dv0 and dv1. (Normally it should not be necessary to do this, as the time is set when the operating system is booted and has an invalid time. Thereafter, the timer facilities in the operating system maintain the current time.)

EnumerateFp(proc) For every file pointer saved by the system (e.g., fpComCm, fpRemCm, etc.), call proc(fp).

CallSwat(s1, s2) This function invokes an explicit "call" on Swat. Either of the arguments that appears to be a Bcpl string will be printed out by Swat.

3.10.1. Routines for Manipulating Bcpl Frames

The following routines case massaging Bcpl frames for various clever purposes such as coroutine linkages. See section 4.7 for a description of the data structures involved.

FrameSize(proc) Returns the size of the frame required by proc.

MyFrame() Returns the address of the current frame.

CallersFrame(f) Returns the address of the frame that "called" the frame f (if f is omitted, the current frame is used).

FramesCaller(f) Returns the address to which the caller of frame f sent control, provided that he made the call with a normal instruction (jsrii, jsri). If error, returns 0.
CallFrame(f, a, b) Sends control to frame f and links it back to this one (i.e., when f returns, the CallFrame call returns). a and b are optional arguments.

GotoFrame(f, a, b) Like CallFrame, but does not plant a return link.

CoCall(a, b) CallFrame(CallersFrame(), a, b)

CoReturn(a, b) Like CoCall, but does not plant return link.

ReturnTo(label) Returns to a given label in the frame of the caller.

GotoLabel(f, label, v) Sends control to the specified label in the specified frame, and passes v in AC0.

RetryCall(a, b) Repeats the call which appears to have given control to the caller with a and b as the first 2 arguments, and the other arguments unchanged. There are certain ways of calling functions which cannot be retried properly. In particular, the address of the procedure must be the value of a static or local variable; it cannot be computed. Thus "a>>proc(s, b)" cannot be retried, but "let pr = a>>proc; pr(s, b)" can be retried.

ReturnFrom(fnOrFrame, v) Looks for a frame f which is either equal to fnOrFrame, or has FramesCaller(f) equal to fnOrFrame. It then cuts back the stack to f and simulates a return from f with v as the value. If error, it returns 0.

3.11. Subsystems and user programs

All subsystems and user programs are stored as "Run files", which normally have extension ".Run". Such a file is generated by Bldr and is given the name of the first binary file, unless some other name is specified for it. The format of an Alto run file is discussed in section 4.8 and in the Bcpl manual.

CallSubsys(S, pause [false], doReturn [false], userParams [0]) will read in a run file and send control to its starting address. If pause is true, then CallSwat("Pause to Swat"); Ctrl-P starts the program. (doReturn will never be implemented, but would have allowed a return to the caller after the closed subsystem "finished.") userParams is a pointer to a vector (length up to 1IUserParams) of parameters which will be passed to the called subsystem. The parameters are formatted according to conventions given in SysDefs.D (structure UPE): each parameter is preceded by a word that specifies its type and the length of the block of parameters; a zero word terminates this list. When the Alto Executive invokes a program with CallSubsys, it passes in userParams an entry with type globalSwitches which contains a list of ASCII values of global switches supplied after the program name.

The open stream is used to load the program into Alto memory according to placement information included in the file. The stream is then closed; no other open streams are affected.

The program is started by a call to its starting address, which will normally be the first procedure of the first file given to Bldr. This procedure is passed three arguments. The first is the 32 word layout vector for the program, described in the Bcpl manual. The second is a pointer to a vector of parameters provided by the caller (the userParams argument to CallSubsys). The third is the "complete file address" (CFA) for a particular point in the file that was used to load the program. If no overlays are recorded in the Run file, this point is the end of file. If overlays are contained in the file, the CFA points to the first word of the first overlay section (this can be used as a hint in a call to OpenFile when loading overlays contained in the same file).

Subsystems conventionally take their arguments from a file called Com.Cm, which contains a string which
normally is simply the contents of the command line which invoked the subsystem (see section 5). The subroutine package GP contains a procedure to facilitate reading this string according to the conventions by which it is normally formatted. This is not a standard routine but must be loaded with your program. (For more information on GP, see the "Alto Software Packages Manual.")

3.12. Finish -- Terminating Execution

When a program terminates operation, it "finishes," returns to the operating system and ultimately to the Executive. A program may finish in several ways:

- **Bcpl return**
  - If the main procedure in the user program (the one invoked by CallSubsys) ever returns, the program finishes. Equivalent to OsFinish(fcOK).

- **Bcpl finish**
  - If the "finish" construct is executed in a Bcpl program, it terminates. Equivalent to OsFinish(fcOK).

- **Bcpl abort**
  - If the "abort" construct is executed in a Bcpl program, it terminates. Equivalent to OsFinish(fcAbort).

- **Swat abort**
  - If, during program execution, the "left shift" key and the "Swat key" (lower-rightmost key on Alto I keyboards, upper-rightmost key on "ADL" Alto II keyboards) are depressed concurrently, the program is aborted. Similarly, if the (control)K ("kill") command is typed to Swat, the program is aborted. Both are equivalent to OsFinish(fcAbort).

- **OsFinish(fcCode)**
  - An explicit call to this function will also terminate execution. The value of fcCode is saved in the static OsFinishCode, which may be examined by the Executive and the next program that it invokes. Values of fcCode presently defined are: fcOK = 0; fcAbort = 1.

When a program finishes, the value of the finish code is first recorded. Then, if the value of the static UserFinishProc is non-zero, the call UserFinishProc(OsFinishCode) is performed before restoring the operating system state. This facility is useful for performing various clean-ups. (Note: To set UserFinishProc, it is necessary to execute @lvUserFinishProc = value.) In order to permit independent software packages to provide for clean-ups, the convention is that each initialization procedure saves the present value of UserFinishProc and then replaces it with his procedure. This procedure will do the cleanups, restore UserFinishProc, and return:

```c
// Initialization procedure
...
static savedUFP
savedUFP = @lvUserFinishProc
@lvUserFinishProc = MyCleanUp
...
```

```c
// The cleanup procedure
let MyCleanUp(code) be
[
... cleanups here
@lvUserFinishProc = savedUFP
]
```

Finally, control is returned to the operating system, which resets the interrupt system, updates the disk allocation table, and invokes the executive anew.
3.13. Junta

This section describes some procedures and conventions that can be used to permit exceptionally large programs to run on the Alto, and yet to return cleanly to the operating system. The basic idea is to let a program deactivate various operating system facilities, and thereby recover the memory devoted to the code and data used to implement the facilities. To this end, the system has been organized in a series of "levels:"

levBasic

Basic resident, including parity interrupt processing, time-of-day maintenance, the resident interface to the Swat debugger, and the initial processing for OsFinish. Important system state is saved here: EventVector, UserName, UserPassword, OsFinishCode. (Approximate size: 1000 words. This portion of the operating system is guaranteed not to extend below address 1750000B.)

levBuffer

The system keyboard buffer (see section 4.6). (Approximate size: 100 words)

levFilePointers

File hints. This region contains "file pointers" for frequently referenced files. (Approximate size: 70 words)

levBcpl

Bcpl runtime routines. (Approximate size: 300 words)

levStatics

Storage for most of the system statics. (Approximate size: 300 words)

levBFSbase

Basic file system "base" functions, miscellaneous routines. (Approximate size: 1500 words)

levBFSwrite

Basic file system "write" functions, the disk descriptor (used to mark those pages on the disk which are already allocated), interface to the time-of-day clock. (Approximate size: 1850 words)

levAlloc

The Alloc storage allocation package. (Approximate size: 660 words)

levStreams

Disk stream procedures. (Approximate size: 2400 words)

levScan

Disk stream extension for overlapping disk transfers with computation. (Approximate size: 400 words)

levDirectory

Directory management procedures. (Approximate size: 1400 words)

levKeyboard

Standard keyboard handler. (Approximate size: 500 words)

levDisplay

Display driver (although the storage for the display bitmap and for the system font lie below). (Approximate size: 1600 words)

levMain

The "Main" operating system code, including utilities, CallSubsys, and the Junta procedure. (Approximate size: 1000 words)

-----

Below levMain, where the stack starts, the system free-storage pool is located. Here are kept stream data structures, the system font, and the system display bitmap. (Approximate size: 6000 words)
This table of levels corresponds to the order in which the objects are located in the Alto memory: levBasic is at the very top; the bottom of levMain is the highest location for the Bcpl stack.

The "Junta" function is responsible for de-activating these levels, thereby permitting the space to be reclaimed. When a program that has called Junta is ready to finish, it calls OsFinish in the normal way. OsFinish performs the "counter-junta," reading in portions of the operating system from the boot file and rebuilding the internal state of those levels that were previously de-activated, and then proceeds with the finish, calling the Executive, etc.

During the counter-junta process (which takes about 1/2 second), the display and interrupt system can continue to be active, provided that the code and storage they use lies below the address that is the value of OsFinishSafeAddr. This permits a token display to remain; also a keyboard handler can continue to sense key strokes and record characters in the system keyboard buffer.

Junta(levName, Proc)  This function, which may be called only once before a "finish" or CounterJunta is done, de-activates all levels below levName. Thus levName specifies the name of the last level you wish to retain. (Manifest constants for the level names are in SysDefs.d.) It then sets the stack to a point just below the retained level, and calls Proc(), which should not return.

The stack present at the time Junta is called is destroyed. The recommended procedure for saving data across a call to Junta is to locate the data below EndCode.

A Junta always destroys the system free-storage pool and does not re-create it. Therefore, open streams, the system display and system font are all destroyed.

It is the user's responsibility to take care not to call operating system procedures that lie in the region de-activated by the Junta. If in doubt, consult the file Sys.Bk, which documents the association between procedures and levels.

...finish...

CounterJunta(Proc)  This function restores all de-activated sections of the operating system, and then calls Proc. The program stack present when CounterJunta was called is destroyed. This function is provided for those programs that do not wish to return to the operating system with a "finish," but may wish to do other processing (e.g., CallSubsys).

After calling Junta, many programmers will wish to restore some of the facilities that the Junta destroys, such as a free storage zone, a display stream, etc. Below is an example of how to go about this. Note that some thought is required because the operating system keeps a separate copy of statics from those referenced in your program. Thus when the OS defaults the third argument of CreateDisplayStream to sysFont, it uses the OS copy of sysFont, not the copy available to your program.

... 

Junta(levXXXXX, Proc) ...

let Proc() be
{
    // Make a new sysZone:
    let v = vec 7035  // You can make it any size
    v = InitializeZone(v, 7035)
    @lvSysZone = v    // Patch the os's version of the static
sysZone = v // Patch my program's version of the static

// Read in the system font again:
let s = OpenFileFromFp(fpSysFont)
let l = FileLength(s)/2
let f = Allocate(sysZone, l)
Reset(s); ReadBlock(s, f, l); Closes(s)
sysFont = f+2 // Patch my program's version of the static
        // Note that because os's version is not patched,
        // I cannot call Ws or otherwise default dsp.

// Make a display stream:
dsp = CreateDisplayStream(6, Allocate(sysZone, 4000), 4000, sysFont)
ShowDisplayStream(dsp, DSalone)

...

3.14. Events

The operating system reserves a small communication region in which programs may record various things. The intended use for this region is the recording of events by one program that deserve attention by another. The Executive cooperates in invoking programs to deal with events posted in the communication region.

Events are recorded sequentially in a table pointed to by the static EventVector. The total length of the table, available as EventVector-1, must not be exceeded by any program generating events. Each event entry (structure EVM; see SysDefs.d) contains a header that specifies the type and length of the entry (length is in words and includes header size); following the header comes type-specific data (eventData). A zero word terminates the event table.

At present, events are defined for:

- **eventBooted**: The operating system has just been booted.
- **eventAboutToDie**: The operating system is about to be flushed, probably to run a diagnostic.
- **eventInstall**: The operating system is to be re-installed. (This event need only be used by the Executive "Install" command.)
- **eventRFC**: A Request For Connection packet arrived. The event data is: Connection ID (2 words), RFC Destination Port (3 words), RFC Source Port (3 words) and Connection Port (3 words).
- **eventCallSubsys**: When the next "finish" occurs, the system will try to execute the file whose name is given as a Bcpl string in the eventData block. If the eventData block has length 0, the system will invoke the copy of Ftp that is squirreled away inside Sys.Boot. Because a "finish" is performed right after the system is bootstrapped, it is possible to InLd Sys.Boot with a message that contains an eventCallSubsys, and thereby to invoke an arbitrary program. See the next section for a description of InLd.
- **eventInLd**: Whenever the next "finish" occurs, the system will call InLd(eventData, eventData). This suggests that the first words of eventData should be an FPRD for a file you wish to InLd.
If a program that generates an event has destroyed the event communication region, it is still possible to pass the event to the operating system. For example, if the memory diagnostic is running and an Ethernet connection request arrives, the mechanism can be used to load the operating system and pass the eventRFC message to it. The mechanism is described in the next section.

3.15. OutLd, InLd, BootFrom

Three functions are provided for dealing with "OutLd" files that record the entire state of the Alto machine. When the operating system is loaded with the "boot" button, such a file restores the machine state exactly as it was at the time of the installation of the operating system. The Swat debugger also uses these facilities, saving the entire machine state on the file "Swatvec" when a break is encountered, and restoring the Swat debugger state from the file "Swatvec".

In the discussion that follows, an FPRD structure is like a file pointer (FP), but the disk address is the Real disk address of the first page of Data in the file.

OutLd(FPRD, OutLdMessage) Saves the state of the machine on the file described by FPRD, which must exist and be at least 255 data pages long. Note that the state saved includes a PC inside OutLd. OutLd returns 0 after writing the file. Unless you know what you are doing, interrupts should be off when calling OutLd (otherwise, OutLd may save some parts of the machine state, such as the ActiveInterrupts word, that was pertinent to an interrupt in progress!).

Programmers should be warned to think carefully about the state that is being saved in an OutLd. For example, the operating system normally saves in memory some state associated with the default disk, sysDisk. If OutLd saves this state on a file, and the program is later resumed with InLd, the state will be incorrect. To be safe, state should be written out before calling OutLd (i.e., WriteDiskDescriptor()), and restored when OutLd returns (i.e., ReadDiskDescriptor()).

InLd(FPRD, InLdMessage) Copies the InLdMessage (length InLdMessage) to a momentarily safe place and restores the machine state from the file described by FPRD, which must have been created by OutLd. Because the PC was in OutLd, OutLd again "returns", but this time with the value 1, and the InLdMessage has been copied into the OutLdMessage. Note: OutLd returns with interrupts disabled in this case.

If the operating system boot file is InLd'ed, the message is assumed to be a legal data structure for the EventVector, and is copied there.

BootFrom(FPRD) This function "boots" the Alto from the specified file. If it is applied to a file written by OutLd, the state of the machine is restored and OutLd "returns" 2 with interrupts disabled. (Note: The effect of this function differs from the effect of depressing the "boot" button. Unlike the boot button, the function in no way initializes the internal state of the Alto processor.)

Some programs (e.g., DMT) will need to know how to simulate InLd or BootFrom:

1. Turn off the display and disable interrupts.
2. Read the first data page of the boot file into memory locations 1, 2, ... #400. If you are loading the installed operating system, the first data page of the boot file is at real disk address 0.
3. Store the label block for the page just read into locations #402, #403, ... #411.
4. (This step applies only if simulating Inl.d.) Now let $msa = rv 2$. This points to a location where a brief message can be stored. Set $msa!0 = 1$. Then for $i = 0$ to $\lceil \text{Inl.dMessage-1} \rceil$ do $msa!(i + 1) = \text{Prototype:ventVector!i}$.

5. Jump to location 3, never to return.

4. Data structures

This section describes the data structures used by the operating system that may be required by users.

4.1. Reserved Memory Locations

The Alto Hardware Manual describes addresses reserved for various purposes. The file AltoDefs.d distributed with the OS declares most of these as manifest constants.

4.2. Streams

The standard data structures for streams are given in the DiskStreams package file "Streams.d". Documentation for the streams package includes a description.

4.3. Disk files

The structure of the Alto file system is described in documentation for the Alto file system (Disks). This includes a description of files, disk formats, directory formats, and the format of the disk descriptor. Bcpl declarations for these objects may be found in the file AltoFileSys.d.

4.4. Display

The data structures used to drive the Alto display are described in the Alto Hardware Manual. The font format for the Alto (.AL format) is also described there. Note that a font pointer such as the one passed to CreateDisplayStream points to the third word of an AL font.

4.5. Zones

A program that wishes to create an operating-system object and retain control over the allocation of storage to the object may pass a "zone" to the operating system function that needs space (e.g., CreateDiskStream). A zone is simply a pointer "zone" to a structure ZN (see SysDefs.d), with $\text{zone} \Rightarrow \text{ZN.Allocate containing the address of the allocation procedure (called by (zone} \Rightarrow \text{ZN.Allocate)(zone, lengthRequested)) and zone} \Rightarrow \text{ZN.Free containing the address of the free procedure (called by (zone} \Rightarrow \text{ZN.Free)(zone, block))}$. The zones created by the Alloc allocator package obey these conventions.

The zone provided by the operating system is saved in the static sysZone. The user may replace the system zone by executing $@lvSysZone = \text{value}$. Subsequent free-storage requirements for the operating system will be addressed to this zone. The system zone is restored when the user program terminates. Warning: The operating system keeps various (and undocumented) information in the system zone, and is unwilling to have the zone changed out from under it. The normal use of lvSysZone is to change the value of sysZone immediately after a call to Junta (which clears away sysZone). If you wish to create disk streams and preserve them across a call to Junta, pass your own zone as an argument to OpenFile.
4.6. Operating System Status Information

A good deal of information is retained in memory that describes the state of the Alto. Much of this information is of relevance to programmers, and is contained in some static scalars:

- **OsVersion**: The version number of the operating system. This number is incremented with each new release of the operating system, incorporating changes however minor.

- **OsVersionCompatible**: The lowest operating system version number believed to be compatible with the present system.

- **UserName**: This static points to a Bcpl-format string that is the user's last name. It is initialized when the operating system is installed on the disk. The maximum length (in words) that the UserName may occupy is recorded in UserNameLen-1.

- **UserPassword**: This static points to a Bcpl-format string that is the user's password, typed to the Executive Login command. The maximum length (in words) that the UserPassword may occupy is recorded in UserPasswordLen-1.

- **SerialNumber**: The serial number of the Alto you are on. This static has proved troublesome, because it is easy to forget that this too will be saved by Outld, and can confuse Ethernet code when it suddenly springs to life months later on a different host half way around the world. Its use is discouraged.

- **AltoVersion**: This static contains the result of executing the VERS instruction. This static has proven troublesome for the same reasons as SerialNumber. Its use is discouraged.

- **sysDisk**: A pointer to the DSK structure, described in Disks.d, which describes the "disk" to be used for standard operating system use. This structure is actually of the format BFSdisk, and contains a copy of the DiskDescriptor data structure. The static diskkd points to this structure alone (structure KD; see AltoFileSys.d). The storage for sysDisk is in levBFSWrite; if you Junta to levBFSbase, you will need to manufacture a new sysDisk structure, by loading and calling BFSInit in your own program.

- **lvsysErr**: This static points to the operating-system copy of the static that contains the address of the error procedure. If you wish to replace SysErr, it suffices to say @lvsysErr = Replacement. Note that some procedures may have already copied the value of SysErr (e.g., when a stream is created, the value of SysErr is copied into the ST.error field in most cases).

- **lvpParitySweepCount**: This static contains the address of the highest memory location examined when sweeping memory looking for parity errors. If no parity checking is desired, set @lvpParitySweepCount = 0.

- **lvpParityPhantomEnable**: This static points to a flag that determines whether phantom parity errors will invoke Swat (a phantom parity error results from a parity interrupt that can find no bad locations in memory). @lvpParityPhantomEnable = 0 will disable phantom reporting.
ErrorLogAddress

This static points to a network address of a spot where error reports (for such things as parity errors) should be sent. The structure is a "port," as defined in Pup documentation.

ClockSecond

This static points to a double-precision integer that gives the count of number of RCLK ticks (when RCLK is viewed as returning a 32-bit number) in a second. This number is used for keeping time, and is nominally 1680000. If timekeeping is extremely critical, you may wish to calibrate your Alto and change this number.

File Hints

The operating system maintains file pointers for several commonly-used files. Using these hints in conjunction with OpenFile will substantially speed the process of opening streams. The files and file pointers are:

<table>
<thead>
<tr>
<th>SysDir</th>
<th>fpSysDir</th>
</tr>
</thead>
<tbody>
<tr>
<td>SysBoot</td>
<td>fpSysBoot</td>
</tr>
<tr>
<td>DiskDescriptor</td>
<td>fpDiskDescriptor</td>
</tr>
<tr>
<td>User.Cm</td>
<td>fpUserCm</td>
</tr>
<tr>
<td>Com.Cm</td>
<td>fpComCm</td>
</tr>
<tr>
<td>Rem.Cm</td>
<td>fpRemCm</td>
</tr>
<tr>
<td>Executive.Run</td>
<td>fpExecutive</td>
</tr>
<tr>
<td>SysFont.AI</td>
<td>fpSysFont</td>
</tr>
</tbody>
</table>

Keyboard Buffer

Although the system keyboard buffer is normally managed by the keyboard handler provided in the system, some programs may want to operate on it themselves. The most important instance of this is when a program that has done a Junta is finishing: if the program keeps its keyboard handler enabled, any characters typed during the counter-junta can still be recorded in the system buffer, and thus detected by the first program to run (usually the Executive).

The static OsBuffer points to a structure OsBUF (see SysDefs.d) that controls access to the buffer:

\[
\begin{align*}
\text{OsBuffer} & \gg \text{OsBUF.First} \\
\text{OsBuffer} & \gg \text{OsBUF.Last} \\
\text{OsBuffer} & \gg \text{OsBUF.In} \\
\text{OsBuffer} & \gg \text{OsBUF.Out}
\end{align*}
\]

First address of the ring buffer
Last address of the ring buffer + 1
"Input" pointer (place to put next item)
"Output" pointer (place to take next item)

The following code can be executed with interrupts on or off to deal with the buffer:

\[
\begin{align*}

#176777 This location, the last in memory, points to the beginning of the area used to save statics for lvBasic through lvBcpl. The file Sys.Bk documents offsets from this number where the various statics will be found.

4.7. Swat

The operating system contains an interface to the Swat debugger (described in the "Alto Subsystems" manual). This interface uses OutLd to save the state of the machine on the file "Swatec," and InLd to restore the state of the machine from the file "Swat," which contains the saved state of the debugger itself. The inverse process is used to proceed from an interrupt or breakpoint. Two aspects of the Swat interface are of interest to programmers:

LvAbortFlag

If @lvAbortFlag is zero, holding down the <left-shift> and <B3> keys will simulate the call OsFinish(feAbort), thus terminating execution of the running program. In critical sections, setting @lvAbortFlag to a non-zero value will disable aborts. The standard convention is to increment @lvAbortFlag when entering such a section and to decrement it when exiting. This permits separate software modules to use the feature concurrently.

LvSwatContextProc

Although Swat saves and restores the state of the standard Alto I/O devices, it has no way to know about special devices attached to the machine. The programmer may arrange that a piece of code will be called whenever Swat is trying to turn off I/O preparatory to calling OutLd, or trying to restart I/O after anInLd. If the programmer does @lvSwatContextProc=DLSProc, Swat will execute DLSProc(0) when turning off I/O, and DLSProc(-1) when turning it on. Since Swat can be invoked at any time, the Swat context procedure must be written in machine language and must not assume anything about the state of the machine or any data structures (in particular the Bcpl stack may be in an inconsistent state).
4.8. The Bcpl stack

The Bcpl compiler determines the format of a frame and the calling convention. The strategy for allocating stack frames, however, is determined by the operating system. We begin by describing the compiler conventions, which are useful to know for writing machine-language routines.

A procedure call: p(a1, a2, ...), is implemented in the following way. The first two actual arguments are put into AC0 and AC1 (AC2 always contains the address of the current frame, except during a call or return). If there are exactly three actual arguments, the third is put into F.extraArguments. If there are more than three, the frame-relative address of a vector of their values is put there (except for the first two), so that the value of the i-th argument (counting from 1) is frame>>F.extraArguments!(frame+i). Once the arguments are set up, code to transfer control is generated which puts the old PC into AC3 and sets the PC to p. At this point, AC3!0 will be the number of actual arguments, and the PC should be set to AC3+1 to return control to the point following the call.

A procedure declaration: let p(f1, f2, ...) be ..., declares p as a static whose value after loading will be the address of the instruction to which control goes when p is called. The first four instructions of a procedure have a standard form:

```
STA 3 1,2 ; AC2>>F.savedPC = AC3
JSR @GETFRAME
<number of words needed for this procedure's frame>
JSR @STOREARGS
```

The Bcpl runtime routine GETFRAME allocates storage for the new frame, NF, saves AC2 in NF>>F.callersFrame field, sets AC2 to NF, and stores the values of AC0 and AC1 (the first two arguments) at NF>>F.formals!0 and 1. If there are exactly three actual arguments, it stores the third one also, at NF>>F.formals!2. Then, if there are three or fewer actual arguments, it returns to L.+3, otherwise it returns to L.+2 with the address of the vector of extra arguments in AC1; at this point a JSR @STOREARGS will copy the rest of the arguments. In both cases, the number of actual arguments is in AC0, and this is still true after a call of STOREARGS. A Bcpl procedure returns, with the result, if any, in AC0, by doing:

```
JMP @RETURN
```

to a routine which simply does:

```
LDA 2 0,2 ; AC2=AC2>>F.callersFrame
LDA 3 1,2 ; PC=AC2>>F.savedPC+1
JMP 1,3
```

The information above is a (hopefully) complete description of the interface between a Bcpl routine and the outside world (except for some additional runtime stuff which is supplied by the operating system). Note that it is OK to use the caller's F.Temp and F.extraArguments in a machine-language routine which doesn't get its own frame, and of course it is OK to save the PC in the caller's F.savedPC.

The operating system currently allocates stack space contiguously and grows the stack down. To allocate a new frame of size S, it simply computes NF = AC2-S-2 and checks to see whether NF > EndCode. If not, there is a fatal error (Swat breakpoint at finish+1); if so, NF becomes the new frame. (Note: the "-2" in the computation is an unfortunate historical artifact.)

4.9. Run files

The format of a file produced by Bldr to be executed by CallSubsys is described by the structure definition SV in BCPLFiles.d. Consult the Bcpl manual (section on Loading) for interpretations of the various fields and the handling of overlays.
5. The Executive

The Alto Executive is itself a subsystem and lives on the file Executive.Run; if you don't like it, you can write your own. It is currently invoked from scratch after the operating system is booted, and whenever a subsystem returns. The Executive is fully documented in the "Alto Subsystems" manual.

6. Operating Procedures

6.1. Installing the operating system

The "Install" command causes the operating system to execute special code which completely initializes the system. The options of the install procedure are controlled by prompts. Installation is needed:

- When a new version of the operating system is distributed. New versions are called "NewOS.boot" (or "NewOsV.boot", the variant that supports the file version numbering facility). You should transfer NewOS.boot to your disk and install it by saying "Install NewOS.Boot". It will ask you several questions which determine it's configuration on your disk ("SysGen", if you will pardon the expression) and finally the Executive will be invoked. The newly configured OS writes itself on the file Sys.boot, so you can delete NewOS.boot after installing.

- When you wish to ERASE a disk completely and re-initialize it. This option pauses to let you insert the disk pack you want initialized. This "new disk" function is invoked by answering affirmatively the question "Do you want to ERASE a disk before installing?" after answering affirmatively that you want the "Long installation dialogue". See also the NEWDISK section of the Alto Subsystems Manual.

- When you wish to change the "user name" or "disk name" parameters of the operating system. The install procedure will prompt for these strings. It is also possible to specify a disk password that will be checked whenever the operating system is booted.

- When you wish to enable the "multiple version" feature of the file system. (Because few programs presently cope with all the subtleties of this feature, it is wise to leave it disabled.)

- When you wish to extend a file system. Basic disks are often kept on Interim File Systems from which users can copy them with CopyDisk. They are usually configured for a single Diablo model 31 disk. If your machine has more disk space, you can extend the file system by answering "Yes" to the question "Do you want to extend this file system?" (this is also part of the "long installation dialog").

6.2. How to get out of trouble

It occasionally happens that a disk will not boot, or something runs awry during the booting process. In this case, the following steps should be considered:

1. Run the Scavenger. This can be done in two ways:

   Place a good disk in the Alto, and invoke the Scavenger. When it asks if you wish to change disks, respond affirmatively, put the damaged disk in the machine and proceed when the drive becomes ready.

   If you have network access to a "boot server", hold down the <BS> and <> keys and push the boot button. Continue to hold down <> until a tiny square appears in the middle of the screen. You should now be talking to the Network Executive; type Scavenger<cr>.
When the Scavenger finishes, the attempt to invoke the Executive may fail because Scavenger was invoked from another disk. Try booting. If unsuccessful, go on to step 2.

2. Use Ftp to get fresh copies of SysFont.al and Executive.Run. Again, this can be done in two ways:
   Place a good disk in the machine and invoke Ftp. After it is initialized, change disks, wait for the damaged one to become ready, and type the necessary Ftp commands to retrieve the files.

   Invoke Ftp via the Network Executive as in step 1.

   Now try booting. If unsuccessful, go to step 3.

3. Install the OS. You guessed it; this can be done in two ways:
   Place a good disk in the Alto and type "Install." When asked for your name, place the damaged disk in the machine, wait for the drive to become ready, and proceed.

   Invoke the "NewOS" via the Network Executive. You will be asked: "Do you want to INSTALL this operating system?"

6.3. File Name Conventions

Various conventions have been established for Alto file names. The conventions are intended to be helpful, not authoritative.

1. All files relating to a subsystem "Whiz" should have file names of the form "Whiz.xxx", i.e. typing "Whiz.*" to the Executive should list them all, delete them all, etc. Example: Bcpl.Run, Bcpl.Syms, etc.

2. File extensions are of preference chosen to be language extensions, i.e. they specify the language in which they are written. The present set is:

   | Bcpl  | Bcpl source code             |
   | Mu    | Micro-code source            |
   | Asm   | Assembler source code        |
   | Mesa  | Mesa source code             |
   | Help  | A help file for the system given in the name |
   | Cm    | A command file for the Alto Executive |

3. File extensions are otherwise chosen to reflect the format of the file. The present set is:

   | Bravo | Text file with Bravo format codes |
   | Run   | Executable file produced by Bldr |
   | Image | Executable file produced by Mesa |
   | AI    | Alto format font file           |
   | Boot  | A file that can be booted       |
   | Br    | Bcpl relocatable binary file    |
   | Syms  | Bldr symbol table output        |
   | BCD   | Mesa object code                |
   | Dm    | File produced by the Dump command, read by the Load command |
   | Ts    | Text file containing a transcript |
   | Disk  | disk image CopyDisk format      |
   | "     |                                |
6.4. Miscellaneous information

The key in the lower right corner of the keyboard on a Microswitch keyboard (<blank-bottom>) or in the upper right on an ADL keyboard (F1) is called the Swat key. If you press it, as well as the <ctrl> and <left-shift> keys, the Swat debugger will be invoked. If you do this by mistake, <ctrl>P will resume your program without interfering with its execution, and <ctrl>K will abort your program.

You can force an abort at any time by depressing the Swat key together with the <left-shift> key.

In order for the operating system to run properly, the following files should be on your disk (those marked * are optional):

<table>
<thead>
<tr>
<th>File</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>SysDir</td>
<td>System directory.</td>
</tr>
<tr>
<td>DiskDescriptor</td>
<td>Disk allocation table.</td>
</tr>
<tr>
<td>SysFont.AI</td>
<td>System display font.</td>
</tr>
<tr>
<td>Executive.Run</td>
<td>Executive (command processor).</td>
</tr>
<tr>
<td>Sys.Boot</td>
<td>Boot-file containing the operating system.</td>
</tr>
<tr>
<td>Sys.Errors</td>
<td>* Error messages file.</td>
</tr>
<tr>
<td>Swat</td>
<td>* Debugger program, created by running InstallSwat.</td>
</tr>
<tr>
<td>Swatee</td>
<td>Debugging file essential to Swat.</td>
</tr>
</tbody>
</table>

(Note: If you wish to change the font used by the operating system, it suffices to copy a new font to SysFont.AI and boot the system.)

If you intend to write programs that use the operating system facilities, you will want some additional files:

<table>
<thead>
<tr>
<th>File</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Sys.Bk</td>
<td>Required by Bldr to load programs that reference operating system functions. This file also shows which functions are implemented in which levels and the names of source files for the code.</td>
</tr>
<tr>
<td>SysDefs.d</td>
<td>Definitions of standard system objects. You will probably want to &quot;get&quot; this file in Bcpl compilations that use operating system functions extensively.</td>
</tr>
<tr>
<td>Streams.d</td>
<td>Data structure definitions relating to streams.</td>
</tr>
<tr>
<td>AltoFileSys.d</td>
<td>Data structure definitions relating to files.</td>
</tr>
<tr>
<td>Disks.d</td>
<td>* Data structure definitions relating to the &quot;disk&quot; object.</td>
</tr>
<tr>
<td>AltoDefs.d</td>
<td>Definitions of places and things peculiar to an Alto.</td>
</tr>
<tr>
<td>BcplFiles.d</td>
<td>* Definitions of the formats of Bcpl-related files.</td>
</tr>
<tr>
<td>Name</td>
<td>Opcode</td>
</tr>
<tr>
<td>--------</td>
<td>--------</td>
</tr>
<tr>
<td>CYCLE</td>
<td>60000</td>
</tr>
<tr>
<td>JSR</td>
<td>64400</td>
</tr>
<tr>
<td>JSRIS</td>
<td>65000</td>
</tr>
<tr>
<td>CONVERT</td>

Table 2.2: Properties of Alto disks
LastMemLoc Last memory location
StartSystem Base of system
StackBase Root of stack; stack extends downward from here
StackEnd Top of stack, which grows down
EndCode End of user program + 1

... This space contains user code and statics, loaded as specified by the arguments to Bldr. Default is to start at StartCodeArea and load statics into the first 400 words, and code starting at StartCodeArea+400. See Bcpl manual.

StartCodeArea Start of user program area
400-777 Page 1: machine-dependent stuff (see Alto Hardware Manual)
300-377 Bcpl runtime page 0
20-277 User page 0
0-17 Unused

Table 3.1: Memory layout (all numbers octal); see section 3.6

LastMemLoc The operating system described in this document runs on 64K
StackEnd Altos; this location is 176777.
EndCode The address of the frame in which the current procedure is
StartCodeArea executing is computed by the MyFrame procedure; alternatively,
compute lv (first argument of current procedure) -4

Table 3.2: Values of symbolic locations in Table 3.1
(all numbers octal)
Operating System Change History

This file contains an inverse chronological listing of changes to the Alto operating system.

The "normal way" to install a new operating system is to retrieve a copy of the files NewOS.Boot, Sys.Sysms, Sys.Errors and Sys.Bk that are being distributed. Say "Install NewOS.boot" to the Exec, answer the configuration questions and then delete NewOs.Boot.

Version 19/16 -- December 15, 1980

Additions: The major addition is that you can now erase a disk and format it to use 14 sectors per cylinder on D0s and Dorados. It is not possible to extend a 12 sector file system to 14 sectors "in place"; you must save your files, erase the disk and restore them.

Changes: [BFSInit] The OS refuses to boot when only one disk of a double disk file system is spinning. It can also detect certain other blunders like DP1 containing a single disk file system rather than the second half of the filesystem starting on DP0. It is not possible to detect all bad cases. [KeyStreams] the static kbTransitionTable is not exported to users who wish to modify the OS's treatment of the keyboard. [DspStreams] it used to be that character codes below 40h unconditionally called the stream scroll procedure. Now, if the character has a non-zero width or height it is displayed. Only characters with zero width and height (CR and LF in particular) call scroll.

Version 18/16 -- May 5, 1980

Additions: The major addition is that you can now extend a file system by reinstalling the OS. A single model 31 file system can be extended to a double model 31, a single model 44 or a double model 44, and a single model 44 can be extended to a double model 44. This is accomplished by a subdialog of the 'long installation dialog'.

Changes: [Calendar] D0s and Dorados now use Alto I clock format. [Dirs] A bug in the 'CompareFn' feature has been fixed. [BFS] 'return on check error' is handled better. [InOut.d] Disk error recovery during InLd and OutLd has been improved. [DiskStreams] A bug in FilePos, introduced in OS17 and responsible for problems with long files in FTP, has been fixed. CleanupDiskStream now does the proper thing if a file is extended to a multiple of the page size and then trimmed back by less than a page. [DisplayStreams] EraseBits is much faster now because it uses BitBit. [BfsMl] BitBit calls Swat if the BBT starts at an odd address.

Version 17/16 -- September 9, 1979

The most significant improvements are that the DSK object has been extended to permit disk-independent operation at the DoDiskCommand/GetCb level; procedures have been added to scan a disk stream at full disk speed; and the directory lookup procedures have been modified to take advantage of these facilities and thereby improve performance substantially. To make way for these improvements, all support for file version numbers (a little-used feature) has been removed.

Incompatibilities are confined to those programs that create DSK objects, since several of the OS routines now expect to be passed the extended versions. Programs that include the TFS must be reloaded with the latest release of TFS; they will then run under OS 17 or OS 16. Programs that include BFSInit must be reloaded with the OS 17 version of BFSInit; they will then not work under previous OS releases. Of the standard Alto subsystems, FTP falls into the first category and Neptune in the second.

In the DSK object, the fields fpDiskDescriptor, driveNumber, retryCount, and totalErrors have moved, and fpSysLog has been deleted; it is believed that no existing programs are affected by this.

Additions: [BFS] the DSK object is extended to include generic procedures InitializeDiskCBZ, DoDiskCommand, GetDiskCb, and CloseDisk, and constants lengthCB and lengthCBZ. The CBZ
Alto Operating System

May 5, 1980

structure is now public, and is defined in Disks.d and documented in the "Disks and BFS" description. InitializeDiskCBZ defaults its errorRtn argument. DoDiskCommand has an optional nextCB argument. DefaultBfsError:Rtn and BfsNonIxFx are exported in Sys.blk, so user programs can load BfsInit. The BFS can now operate in any of the file system partitions available on the large disks of Dorados and DOS. An optional hintLastPage argument to ActOnDiskPages, WriteDiskPages, and DeleteDiskPages has been added. New procedures Min, Max, Umin, Umax, and Call10 through Call15.

[Disk streams] A DiskStreamsScan level has been added, containing the procedures InitScanStream, GetScanStreamBuffer, and FinishScanStream; these support overlapped reads at full disk speed.

Deletions: The remaining vestiges of the Sys.Log code are gone. BFSSetStartingVDA removed -- use ReleaseDiskPage(disk, AssignDiskPage(disk, desiredVDA-1)). All support for version numbers has been removed from the standard release; an alternate release (NewOsV.boot) is available in which the version number facility has been retained, but it does not benefit from the improved directory lookup performance, it is somewhat larger, and it may not be supported in the future.

Changes: levBasic is now guaranteed to be at 175000B or higher, for the benefit of Mesa and Smalltalk. ReleaseDiskPage doesn't increment the page count if the page released is already free. The BFS now retries data-fail errors indefinitely. The BFS cleanup routine is now called with three arguments. The DiskDescriptor file is now allocated next to SysDir rather than in the middle of the disk as it was in OS 16. The old write date is not restored to a directory file (directory bit on in serial number) if the file is opened for writing but never dirtied. A number of bugs in the disk streams code have been fixed that prevented manipulation of files greater than 32767 pages long. Directory operations (OpenFile, DeleteFile, etc.) now search the directory at essentially full disk speed. Booting has been speeded up somewhat. The OS uses and maintains disk shape information as a DFSHARE file property in the leader page of SysDir.

Version 16/16 -- February 19, 1979

This version contains many internal changes but few external ones. Even though it is technically incompatible with previous releases (OS 16/16 rather than OS 16/5), most programs are not affected. There are three major changes: 1) backward compatibility for the "old" OS has been removed, 2) the disk bit table is now pagd rather than occupying a fixed area in memory, and 3) the interface between Swat and the OS changed - Swat.25 is required.

Additions: the BitBlt instruction is accessible from Bepi and a structure definition for a BitBlt table was added to AltoDefs.d. More of the page 1 and IO area location names were added to AltoDefs.d. A new declaration file, BepiFiles.d, was created and the Bepi file format definitions were moved there from SysDef.d. The OS corrects parity in extended memory banks during booting. The "new" file date standard is implemented. The DDMgr object operations were added to Calls.asm.

Deletions: the compatibility package has been removed. All of the commonly used subsystems which depended on it have been updated. They are: Asm, RamLoad, CleanDir, EDP, and Scavenger. If you keep any of these on your disk, you should get new copies from the <Alto> directory. fpSysLog, fpSysTs, fpWorkingDir, faSysLog, and nameWorkingDir went away.

Reorganizations: the BFS was extensively reorganized to bring it into sync with the TFS. The code for creating a virgin file system and creating a DSK object has been disentangled from OS initialization. The Bepi frame-munging code was split out of BFSML.asm and put into a new file: BepiTricks.asm. Initialization for the keyboard was moved from the OS initialization modules into KeyStreamsB.bepi, making it self-contained. Parity Error handling, Calendar clock update, Swat interface, and InOutLd were split into separate modules.

Changes: DisableInterruption returns true if interrupts were on. The VERS and DCB structure were moved into AltoDefs.d. The names of many OS modules changed. The long installation dialog permits more precise control over the handling of memory errors. The erase disk dialog permits you to create an extra big directory. The interface to Swat has changed - Swat.25 is the new version.

Version 15/5 -- March 15, 1978
Fixed a bug in the file date code; introduced another bug in the same code.

Version 14/5 -- March 1, 1978

Additions: ReadCalendar and SetCalendar - analogous to DayTime and SetDaytime only they conform to the new time standard. DayTime and SetDaytime will continue work correctly until April 30, 1978. A new declaration file, AltoDefs.d was created; some things were moved there from SysDefs.d. Definitions of the format of .BB (overlay), and .Syms files were added to SysDefs.d. This OS has room for a 'big' bittable - a special OS version is not required.

Deletions: The system log was de-implemented. LogOpen, LogClose, and MakeLogEntry are now Noops. They will be removed when an incompatible OS is next released.

Reorganizations: Noop, TruePredicate and FalsePredicate were moved from StreamsML.asm to BFSML.asm (up a few Junta levels). Fast streams were split out of disk streams: FastStreamsB.bcpl and FastStreamsA.asm. Streams.bcpl was split into 3 files: DiskStreams.bcpl, DiskStreamsMain.bcpl, and DiskStreamsAux.bcpl; StreamsML.asm disappeared.

Changes: A bug in ReturnFrom was fixed (this only matters if you use the microcode version of the frame allocator). TruePredicate now returns -1 (it used to return 1). If the unrecoverable disk error routine in the BFS returns, the cleanup procedure is called and things plunge on. OpenFile with a filename containing a non-existent directory now returns 0 instead of calling Swat. The Diablo printer bits (0-7) are now ignored by the keyboard interrupt routine.

Version 13/5 -- May 16, 1977

Additions: ParseFileName (a lower level directory function) was made available to users.

Changes: Minor, yea insignificant bugs fixed.

Version 12/5 -- March 20, 1977

Additions: ClockSecond. Location 613b is now reserved to indicate to RAM microcode what sort of Alto we are on: 0 implies Alto I; -1 implies Alto II.

Changes: Time-keeping accuracy improved slightly. BFS is now reentrant--you may have several independent disk activities going concurrently (this will make CopyDisk more reliable).

Version 11/5 -- January 9, 1977

Additions: eventInLd and eventCallSubsys processing added. Also now possible to install the operating system with logging disabled.

Changes: Booting process somewhat more robust. Several changes to improve diagnostic information about parity errors provided by Swat. Improved password protection. Alto II fixes in parity and timer routines.

Version 10/5 -- November 2, 1976

Changes: A nasty bug in the disk routines was uncovered and fixed. It was responsible for occasionally garbaged files.

Version 9/5 -- September 25, 1976

Additions: verNewAlways option to OpenFile; changeSerial entry on file leader pages.

Changes: Various bugs relating to keeping file version numbers were fixed.

Version 8/5 -- August 28, 1976
Changes: Several bugs in parity error detection and reporting were removed.

Version 7/5 -- August 10, 1976

Additions: The Idle procedure and corresponding static lvIdle; lvParityPhantomEnable global static; more installation options.

Minor changes: Two bugs in PositionPage are fixed -- one permitted read-only files to be accidently lengthened.

Version 6/5 -- July 8, 1976

Additions: (1) Several global statics have been added: AltoVersion (code for machine, build and microcode versions), ErrorLogAddress (Ethernet address to report hardware errors), #176777 points to the global statics.

(2) The format of Sys.Boot has been altered slightly so that Altos may be booted over the Ethernet.

Version 5/5 -- April 28, 1976

How to get it: Because version 5 introduces some incompatibilities, it is essential that several subsystems be updated: (1) get a new Executive and Bravo 5.5 or later (these will run under version 4 or version 5 of the operating system); (2) get Sys.Bk, Sys.Syms, Sys.Boot (under another name, e.g. NewOs.Boot); (3) install your new system; (4) get a new version of DDS, which depends on version 5 of the operating system; (5) get a new InstallSwat.Run and invoke it; (6) if you are a programmer, be sure to get new copies of all definitions files (e.g. AltoFileSys.d).

Incompatibilities: (1) Most calling sequences and subroutine names for the "Bfs" routines have changed. These changes were made in order to introduce the concept of a "disk" object, so that standard OS stream and directory functions could be applied to non-standard disks (e.g., the Trident T80). The static lvDiskKd has been removed.

(2) The "disk address" returned as part of a CFA or FA is now a virtual disk address. The routine RealDiskDA can be used to convert it to a physical disk address if desired.

Minor changes: (1) The handling of the UserFinishProc has changed. The recommended procedure for such procedures is to simply return from a finish procedure, not to call OsFinish again.

(2) Several bugs in the streams package are fixed, e.g. ReadBlock applied to a file with 511 bytes in the last data page did not work correctly.

(3) The "new disk" refreshing procedure has been changed to use the new FTP; it is now mandatory that this file be present on your disk when you attempt to make a brand new disk.

(4) It is now possible to change disk packs during the Install sequence; simply change packs when some question is asked of you (exception: if you are creating a "new disk," do not change packs until told to do so).

(5) The log functions have been made much more robust. It is now possible to delete Sys.Log and continue operations.

(6) Numerous bugs in ReturnFrom and FramesCaller are fixed.

(7) The default number of file versions to keep is now stored in the DiskDescriptor.

(8) Wns has been changed to allow both signed and unsigned number conversion.

(9) The arguments to DeleteFile have changed slightly (only if you pass more than 2 arguments to it).
(10) The introduction of the "disk" object has added some statics: sysDisk, some functions: KsGetDisk, LnPagingSize, and optional "disk" arguments to disk stream opening functions.
